PAUL BOWDEN, *Consultant Forensic Psychiatrist, Bethlem Royal and Maudsley Hospitals*

Clobazam: Human Psychopharmacology and Clinical Applications. Edited by I. HINDMARSH, P. D. STONIER and M. R. TRIMBLE. Oxford: Oxford University Press for the Royal Society of Medicine. 1985. Pp. 215. £8.00.

This book derives from a symposium on the 1,5 benzodiazepine clobazam. It consists of 30 separate papers almost all of which directly concern the drug. A number refer to studies of performance tests on volunteers, others concern anxiolytic effects and the latter part of the book is about the anticonvulsant effects of clobazam. Several of the studies tend to go over similar ground and indeed this is almost inevitable when so many groups of authors are dealing with a relatively limited subject. Some investigations are well done but many are very small and a few have defects of methodology. They are inclined to be reported in rather excessive detail, for example several authors specified that subjects who were known to be pregnant or suspected of being so were excluded from the study, a precaution that I would have expected to be so customary that it could go without saying. On the other hand the topic of the risks of benzodiazepine prescription does not receive as much emphasis as one might have hoped in a volume entirely concerned with a benzodiazepine for illicit ingestion by polydrug abusers and another mentions a difficulty in obtaining the planned sample size because of local changes in attitude to benzodiazepine prescribing but otherwise the question of the possible problems associated with benzodiazepine use in neurotic patients is scarcely mentioned. The papers on anticonvulsant effects generally concern the addition of clobazam to standard regimes in epileptic patients whose control is poor. The results are conflicting but fortunately the last paper reviews the use of clobazam in epilepsy. Many readers might find a review on the other aspects of

clobazam use more rewarding than the perusal of this volume which at times seems a little like promotional literature. At its price of £8 however some may find it a worthwhile purchase in view of the few very good chapters and perhaps for the insight it offers into the conduct of clinical studies.

EVE C. JOHNSTONE, *Consultant Psychiatrist, Northwick Park Hospital, London*

Family Management of Schizophrenia: A Study of Clinical, Social, Family and Economic Benefits. By IAN R. H. FALLOON *et al.* Baltimore: Johns Hopkins University Press. 1985. Pp. 207. £25.45.

It is now a truism that for all that the major advances of medicine over the last half-century have been based on the intense development of specialist expertise, this has its inevitable limitations. So we move on to the whole world of the individual, to an advocacy of holistic medicine that varies from the trite to the crackpot, only to find that here again there are limitations. Because of the social nature of man, the involvement of the family is a crucial element in any, but especially in any long-term, illness. Not only can the family provide an elaborate mechanism for humiliation or ill-treatment, or indifference, as well as for support, but the family exists in a changing world.

The family as the unit of care is certainly more popular with politicians, for it is likely to be cheap. But when we come to research the performance in family management of an illness like schizophrenia, the difficulties are nothing less than awesome. The fluctuations of the illness require a long-term approach now only attainable in this country with difficulty.

In this important, academically sound and fascinating volume we see the fruits of a decade's study. Dr Falloon describes four major aims: to compare behavioural family therapy and individual supportive psychotherapy after the treatment of a florid exacerbation in patients who lived in a stressful family environment; to assess the changed functioning of family members; to conduct an analysis of the costs of the two approaches; and to analyse the variables that might influence outcome.

There seems, despite suggestions to the contrary of earlier work, to be a series of important advantages accruing from the factual education and enhanced problem-solving skills in families helped to cope with a schizophrenia member. The social benefits for the family were combined with improved functioning of their patient when compared with individual treatment.

The authors provide an admirable review of the literature, keep well away from excessive enthusiasm and provide an elegant and instructive monograph that merits attention and respect from colleagues of all grades of seniority. And like all important research, it raises more fascinating problems for the future.

ERIC WILKES, *Emeritus Professor of Community Care and General Practice, University of Sheffield*

Making Sense of Psychiatric Cases. Edited by MAURICE GREENBERG, GEORGE SZMUKLER and DIGBY TANTAM. Oxford: Oxford University Press. 1986. Pp. 258. £9.95.

This book fills a gap for psychiatrists in training. As the author states, it is necessary to become practised in history taking and mental state examination. The Institute of Psychiatry booklet *Notes on Eliciting and Recording Clinical Information* already provides a detailed structure for history taking. However, until now there has not been a book giving illustrative case histories to complement this.

The authors point out that while at places like the Maudsley much time is spent on history taking, in other places with a more busy work load, junior doctors may find a text book helpful. Following an introductory case concentrating on how to organise and select information there are eleven further case histories covering a wide spectrum of commonly encountered conditions such as depression, schizophrenia, alcoholism and overdoses. Each case history is founded on a genuine clinical case and presented under headings of presenting complaint, family history, personal history, past medical history, past psychiatric history, previous personality, mental state examination, physical examination, summary formulation, diagnosis and etiology, further investigation, management and prognosis. It is rightly emphasised that if the patient is in a too disturbed state on admission to give a family history this should be obtained later and be included in making a comprehensive formulation, a thing junior doctors often neglect.

A criticism of the case histories is that the headings are then repeated twice as a means of following further development of the case. As a result, at times, the descriptions become somewhat obsessively repetitive. For example, in the case of anorexia nervosa, after going into great detail in the initial formulation, as to why the diagnosis was anorexia nervosa, there were two further reformulations in the chapter using the same headings as previously, saying each time that the diagnosis still remained one of anorexia nervosa. Another concern is a more personal one. As both a practising general psychiatrist and analyst, I feel that psychiatrists can get incarcerated in the history taking technique with over application of text book theories in not only making formulations, but then applying them in a logical manner as answers to management. This might stultify development of their own individual sensitivity.

However, it is important to be fully conversant with history taking, mental state examination and making comprehensive formulations including a diagnosis. Often junior doctors try to opt out of committing themselves for formulations. In this context the book is a necessary contribution and should become standard reading for all junior psychiatrists approaching their MRCPsych. examination.

RICHARD LUCAS, *Consultant Psychiatrist, Claybury Hospital, Essex*

Sharing Psychological Skills: Training Non-Psychologists in the Use of Psychological Techniques. A special issue of the *British Journal of Medical Psychology*. Guest editors HILTON DAVIS and PETER BUTCHER. Leicester: The British Psychological Society. 1985. Pp. 96. £6.95.

This 'book' is an edition of the *British Journal of Medical Psychology* published in hardback. It has neither a preface nor a foreword and although a brief index has been added it retains the feel of a journal which for this reader dilutes the enjoyment of the read irrespective of the contents. The common theme of all the contributions is the teaching of psychological skills to non-psychologists with each of the authors actively involved in running training courses.

Some of the papers are essentially a review of the literature while others are anecdotal reports of specific educational programmes. In all there are nine contributions as well as an introduction by the guest editors. Three are on the training of patients or relatives in self-help methods while the remaining six discuss the dissemination of psychological treatment skills to other professional and voluntary caregivers including general practitioners, nurses, hospital medical staff and marriage guidance counsellors. The contents of the teaching programmes outlined in the book range from behaviour modification to basic counselling and from adaptive skills in the elderly to a broad based, 12-week adult education course on 'strategies for living'. In general there is a welcome emphasis on the practical rather than the theoretical aspects of psychological skills training.

While inevitably there is some overlap in a collection of papers of this nature the final selection does have a somewhat arbitrary appearance. Given the constraints on space I would have liked the book to have concentrated either on psychological skills training for various patient groups or alternatively on training for professionals. The book would also have benefited from an introductory paper on the organisational and practical constraints which may substantially affect the quality and quantity of teaching within the Health Service over the next few years. A related issue is discussed in, arguably, the most stimulating paper by Keith Nichols who reminds us that no matter how well we teach psychological skills to general medical and paramedical staff it is only through changes in organisation and practice at ward level and integration of psychological ideas into the medical subculture that the influence of such teaching can be maximised and maintained.

In spite of the rather arbitrary choice of material this book has much to recommend it with most of the contributions being clear, concise and convincing. It will doubtless prove a useful reference source for all of us who are faced with the daunting task of organising, implementing and evaluating a training programme on psychological treatment methods for either patients or colleagues.

ROBIN DAVIDSON, *Top Grade Psychologist, Holywell Hospital, Co. Antrim*

The Psychology of Gifted Children: Perspectives on Development and Education. Edited by JOAN FREEMAN. Chichester: John Wiley. 1985. Pp. 414. £24.75.

This is a volume in the Wiley Series on Developmental Psychology and its Application. The Series Editor, Professor Connolly, describes the book as "... a remarkably diverse set of essays", and this comment rather neatly sums it up. Twenty-two chapters, two of them contributed by Dr Freeman, cover topics as diverse as identifying gifted infants, sleep and mental efficiency, musical and mathematical giftedness, emotional aspects and delinquency, giftedness in Israel and China, and problems in the education of gifted children.

But what is "giftedness"? It still comes as a surprise to this reviewer that the former British Grammar Schools, catering for the most academically able 15 to 20% of the population, were regarded by foreign educators as "schools for the gifted". Are we talking of this able 20% or the most able 1 to 5%? Is giftedness a general ability or are isolated talents to be similarly regarded. As yet, there is no clear consensus, but Eysenck's chapter on 'The Nature and Measurement of Intelligence' provides a masterly, succinct overview of the complexities of the area.

Freeman's own chapter on 'Emotional Aspects of Giftedness' provides the background to and outcome of her own studies. She found that whereas the children whose parents had joined the National Association for Gifted Children were significantly more disturbed than normal controls, equally gifted children identified in schools (but not Association members) were no more deviant than the normal. Nevertheless, children who spend hours studying, practicing musical instruments and the like do have special needs, and these are sensibly discussed.

Less satisfying is Brooks' résumé of his study of 'Bright Delinquents'. His sample appeared to be underachieving academically and to have a high rate of father absence. Otherwise, there was little to distinguish them from the control group.

Overall, the book provides an interesting introduction to an important area. Many questions are raised: few are answered. But in the discussion some fundamental views on our attitudes to the gifted are challenged.

WILLIAM YULE, *Senior Lecturer in Psychology,
Institute of Psychiatry, London*

Behavior and Cancer. By Sandra M. Levy. London: Jossey-Bass. 1985. Pp 257. £28.50.

Although there is still no convincing evidence that psychological factors predispose to the development of cancer in man, animal and epidemiological research increasingly indicate that many factors related to ways of life may be major factors. Psychiatrists have tended to concentrate on a narrow range of psychological variables and have shown less interest in the ways in which personality, mental state and social circumstances affect established primary risk factors, such as diet, smoking and acceptable hazards and sexual activity. It is a virtue of this book that it takes

the wider view. Dr Levy begins from epidemiological and animal evidence and sets behavioural factors in context. Successive chapters review the major risk factors, diagnosis and screening, immune and hormonal mechanisms, behavioural factors contributing directly to the progression of cancer and behavioural implications.

Dr Levy uses standard medical and psychological references, case examples and a somewhat unhappy choice of rather pretentious literary quotations to provide a clear summary of behavioural influences on the onset and progression of cancer and to draw clinical conclusions about screening and treatment. This is a useful exercise and, allowing for some stylistic irritations, a readable introduction to a subject and to literature which has become almost inaccessible to the non-expert. It is, however, a relatively short book and, as is evident in the presentation of the medical background and in the glossary, it is intended for a wide non-medical audience. Psychiatrists will find it informative and a great deal easier to read than other less comprehensive reviews.

RICHARD MAYOU, *Clinical Reader in Psychiatry,
University of Oxford*

Dictionary of Psychiatry. By H. Walton. Blackwell Scientific Publications. 1985. Pp. 170 £12.50

As communication is so fundamental to psychiatry I wonder why we have waited so long for a book of this kind, a compact but reasonably comprehensive dictionary of the subject. The editor has been assisted by a panel of psychiatric dignitaries (mostly professors) so that the definitions are authoritative. The text is also a model of conciseness and clarity. It was a pleasure to range through the definitions, from *birth trauma*, through *dasein* and on to the *death instinct*.

Most of the terms included are much in current use, but requiring definition for all that. However, a few pleasures for lexicologists lurk among the pages. I now know what *geloplegia* and *hypnobia* are. Of course one can always quibble over what should be included in or omitted from a dictionary of this sort. Although the intended readership is wide, including the lay public, some of the inclusions seemed superfluous. Again, certain drugs are included, but the grounds for their selection were unclear to me.

Sometimes the text goes beyond mere definition. For example, we are told that psychiatric treatment is associated with social class, intensive psychotherapy or psychoanalysis being prescribed more often for class 1 and electroconvulsive therapy for class 5. Also brief but fascinating biographical notes are provided on famous figures. Under B the following appear: Bateson, Beers, Binet, Binswanger, Bleuler, Brentano, Breuer, Brill, Barrow, Burt.

I wonder if £12.50 is a little expensive for a book of this size, but none the less I predict this will be a popular book, and deservedly so. I recommend it.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

THE BRITISH JOURNAL OF PSYCHIATRY

October 1986

Vol 149

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrists

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry*, 17 Belgrave Square, London SW1X 8PG.

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al.*, *British Medical Journal*, 7 May 1983, **286**, 1489-1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper**.

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full**. Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in *italic* and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that ...'

DURKHEIM, E. (1897) *Le Suicide*. Paris. Translated (1952) as *Suicide: A Study in Sociology*, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. *British Journal of Psychiatry*, **124**, 352-358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) *Education, Health and Behaviour*. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In *Pathology and Treatment of Sexual Deviation* (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80-110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180-210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

(in conjunction with the Bethlem Royal & Maudsley
Hospitals)

DIPLOMA IN FAMILY AND MARITAL THERAPY

Applications are invited for a training in family therapy leading to a diploma in family therapy. This training will involve a full-time placement of one year's duration. Clinical experience will be gained through honorary clinical attachments to clinical teams in the Bethlem Royal and Maudsley Hospitals (the Joint Hospital). A wide range of clinical experience will be available, including work with families and couples, in child, adolescent and adult settings.

Successful applicants will be expected to take part in the other academic and clinical activities of the Joint Hospital and Institute of Psychiatry, as well as attending regular theoretical and clinical seminars specifically related to family therapy. Video-tape supervision and live supervision will be carried out and students will be expected to carry a clinical load of families and couples under supervision.

The course will be specially addressed to students from psychiatry, social work and clinical psychology. Suitably qualified candidates from other disciplines may be considered.

Requests for further information: (course details, dates, fees, etc.) should be sent to: Dr Justin Schlicht, Psychotherapy Unit, Maudsley Hospital, Denmark Hill, London SE5 8AF UK.

NEW
PUBLICATION

GASKELL

The Publications Section of the Royal College of Psychiatrists
**THE PROVISION OF MENTAL HEALTH SERVICES IN BRITAIN:
THE WAY AHEAD**

Edited by Greg Wilkinson and Hugh Freeman

ISBN 0 902241 15 X

Pp 197

£7.50

Published February 1986

This unique publication indicates the scope of development in mental health service provision over the past two decades and the major challenges to future progress. It is clear that the contribution made by psychiatrists is crucial. But attention is also given to the views and perspectives of the other necessary participants: regional and district health authorities, local authorities, the provisions that make up both psychiatric and primary care, multi-disciplinary teams, families, and voluntary and other non-statutory care-giving agencies, including the private sector.

Orders with cheques should be sent to: Editorial Office, Royal College of Psychiatrists, 17 Belgrave Square, London SW1X 8PG.

Guy's/Charter

4th Annual Symposium on Expatriate Stress

Guy's Hospital and the Charter Clinics are sponsoring the 4th Annual Symposium on Expatriate Stress.

All the speakers have practical experience in dealing with problems related to expatriate stress, or are involved in their prevention, treatment and research.

Papers will be presented by specialists in the fields of psychological and occupational medicine and in personnel management and recruitment, selection and preparation for overseas postings.

The symposium will be held at The Royal College of Physicians in London on **Tuesday 28 October 1986**.

Alcohol: Our Favourite Drug

ROYAL COLLEGE OF PSYCHIATRISTS

Alcohol is the western world's most widely used – and most damaging – drug. In England and Wales alone the total cost of alcohol misuse is more than £1,600 million per year.

This new book is an updated and expanded version of the much quoted *Alcohol and Alcoholism* (1979). New features include sections on causes of excessive drinking; prevention; self-help; workplace problems; and women and alcohol. The book gives a balanced view of the facts about alcohol, carefully defining such terms as 'alcoholic' and 'addict' in the light of recent thinking, and making policy recommendations on drinking and driving and taxation, as well as personal recommendations for safe, risky and harmful weekly intake.

Parasuicide and Unemployment

S. PLATT

The current economic recession in Europe and North America has led to a renewal of interest in the possible consequences of mass unemployment for the nation's health. This annotation assesses the relationship between unemployment and one indicator of morbidity: parasuicide (non-fatal deliberate self-harm). A previously published review of the literature is supplemented by more recent research, particularly from Edinburgh and Oxford.

The relationship between parasuicide and unemployment among individuals

At least twenty studies have been published which include information on the proportion of parasuicides who are unemployed on admission to hospital. A number of these (e.g. Bruhn, 1962; Edwards & Whitlock, 1968; Hawton *et al.*, 1982; Bille-Brahe *et al.*, 1985; Hawton & Rose, 1986) draw attention to the fact that the unemployment rate among parasuicides is considerably in excess of that in the general population. Investigators have also calculated the incidence of parasuicide by employment status, consistently finding higher rates among the unemployed. Thus, in 1982, the parasuicide rate among unemployed men in Oxford was 708 per 100 000, while the equivalent figure for employed men was 46; the relative risk (the ratio of the parasuicide rate among the unemployed to that among the employed) was 15.4 (Hawton & Rose, 1986). In Edinburgh in the same year the parasuicide rates were 1345 and 114 respectively, giving a relative risk of 11.8 (Platt & Kreitman, 1985a). While there has been a downward trend in the parasuicide rate among the unemployed in Edinburgh over the period 1968-1984, the relative risk has fallen below 10 in only three years of the series.

The parasuicide rate among the unemployed tends to increase with longer durations of unemployment. In recent years the relative risk of parasuicide among men unemployed for more than a year (compared with employed males) has ranged between 26 and 36.6 in Oxford (Hawton & Rose, 1986) and 13.5 and 20.4 in Edinburgh (Platt *et al.*, 1985). However, even recent job loss has been shown to be associated with relative risks of considerable magnitude. In Edinburgh the relative risk among those unemployed for less than four weeks has not fallen below 4.3 during the years 1982-84.

The Edinburgh and Oxford data sets also permit the calculation of parasuicide rates among males after controlling for possible confounding effects,

such as age, social class and area of residence. In both cities, unemployed men of all age groups show elevated relative risks compared with the employed. The highest parasuicide rates among the unemployed are found in the 30-49 age group in Oxford and in the 25-54 age group in Edinburgh (Hawton & Rose, 1986; Platt, 1985). Among both employed and unemployed in Edinburgh an inverse relationship between parasuicide and social class was evident, with highest rates in social class V (Registrar-General, 1980). The relative risk of parasuicide among the unemployed was significantly high in each social class group, ranging from 8.4 in class IV to 29.0 in classes I and II. While there was considerable variation in parasuicide rates by employment status across different geographical areas of Edinburgh, the lowest relative risk (7.4 in 1970-72 and 4.4. in 1980-82) was significantly greater than zero (Platt & Kreitman, 1985a).

It is noteworthy that in Edinburgh the highest relative risks are found in the years (1968-74), social classes (I and II), age groups (55 years plus) and areas (with above average proportions of professionals and owner-occupiers) characterised by the lowest rates of unemployment; i.e. there is a marked tendency for the relative risk to fall as the unemployment rate rises. Nevertheless, an analysis of trends in population-attributable risk shows that in recent years as much as half of the overall parasuicide rate in Edinburgh may be "attributable" to unemployment, since the declining rate of parasuicide among the unemployed over the years has been more than offset by the increase in the numbers at risk. In consequence, the absolute numbers of unemployed parasuicides and the proportion they form of all hospitalised parasuicides have increased steadily over the period (Platt & Kreitman, 1985a).

Personal characteristics of employed and unemployed parasuicides

In their study of male parasuicide patients admitted

to the general hospital psychiatric service in Oxford, Hawton & Rose (1986) showed that, compared with the employed, the unemployed were significantly more likely to be psychologically vulnerable, i.e. to have received psychiatric treatment in the past, to be in treatment at the time of the parasuicide episode, to be diagnosed alcoholic, and to be parasuicide repeaters. Platt & Duffy (1986) examined correlates of joblessness in two cohorts of first-ever male parasuicides: one admitted to the Regional Poisoning Treatment Centre (RPTC) in Edinburgh during the years 1969–71 (a period of relative prosperity), and the other admitted to the RPTC during 1980–83 (a period of economic recession). Overall, the unemployed were significantly more likely to be unmarried, to live alone or in an institution, to have experience early separation from their mother, to have received psychiatric treatment, to be given a diagnosis of abnormal personality, to have a criminal record, to be in serious debt, and to misuse drugs habitually. These differences appeared to be unaffected by the prevailing economic climate.

A further examination of variation in personal characteristics among parasuicides was undertaken by Platt (1986). In a cohort of unemployed male first-ever parasuicides admitted to the RPTC in 1982–83, significant differences by duration of unemployment were found on four of the response variables: civil state, age, personality diagnosis, and receipt of psychotropic medication. While there was no clear duration-related trend in respect of civil state or age, longer durations of unemployment were significantly associated with a greater prevalence of personality abnormality and receipt of psychotropic medication. Hawton & Rose (1986) also state that in their cohort of male parasuicides admitted in Oxford, significantly more of the long-term unemployed (compared with the short-term unemployed) are psychologically vulnerable. However, no data are provided.

In a third study from Edinburgh, Platt & Dyer (1986) measured variation in psychological features associated with unemployment among a sample of economically active male parasuicides admitted to the RPTC in 1979. Employed and unemployed individuals did not differ in the degree of suicidal intent, but the unemployed were significantly more likely to be depressed and to describe feelings of hopelessness. Even after partialling out the effect of depression, the unemployed remained more hopeless.

The ecological relationship between parasuicide and unemployment

Analyses of the relationship between unemployment and parasuicide rates across geographical areas have

revealed a significant positive correlation in Brighton, 1966–68 (Bagley *et al.*, 1973) and in Edinburgh, 1968–73 (Buglass & Duffy, 1978). Platt & Kreitman (1984, 1985a) correlated male unemployment and parasuicide rates across 23 electoral wards (1970–72) and 31 regional electoral divisions (1980–82) in Edinburgh. In both periods the ecological correlations were highly significant ($r=0.76$, $P<0.001$ in 1970–72; $r=0.95$, $P<0.001$ in 1980–82); the increase in correlations over the decade was also significant ($P<0.001$). Platt & Kreitman (1985a) further examined the relationship between unemployment and parasuicide to determine if the connection between them could be ascribed to common third factors such as social class and poverty. Partialling out the effect of variations in the social class composition of the city districts reduced the magnitude of the observed correlations (from 0.76 to 0.51 in 1970–72 and from 0.95 to 0.81 in 1980–82), but the resulting correlations remained significant for both periods. On the other hand, after controlling for the level of poverty the partial correlation in 1970–72 fell to a non-significant level ($r=0.13$) (data were not available to perform this analysis for 1980–82.) Thus unemployment appears to be associated with parasuicide only in so far as it relates to poverty or to some other variable closely connected with poverty.

Forster & Frost (1986) report a substantial (but not statistically significant) correlation between the medical self-poisoning rate (based on persons age 15–44 years admitted to hospital because of adverse effects of medical agents) and the unemployment rate across 12 regional health authorities in England and Wales in 1978 ($r=0.57$, NS). A multiple regression analysis performed on the medicinal self-poisoning rate as the dependent variable and the psychotropic prescription rate, unemployment rate and admissions capacity rate (a measure of bed availability) as the independent variables demonstrated that only the psychotropic prescription rate met the criteria for retention in the equation.

Only three reports are available on the relationship between unemployment and parasuicide rates over time. Among Edinburgh male residents the temporal association was found to be significantly positive overall ($r=0.62$, $P<0.02$) during the period 1968–83. It should be noted, however, that the relationship between unemployment and parasuicide over the first eight years of the period was strikingly different to that found over the final eight years: it was positive between 1968 and 1975 ($r=0.92$, $P<0.01$); and negative between 1976 and 1983 ($r=-0.67$, NS) (Platt, 1985). In Hartlepool during the period 1974–83 the unemployment rate quadrupled while the parasuicide rate (as measured by

hospital admissions diagnosed as principally suffering from toxic effects of drugs or chemicals) remained fairly constant ($r = 0.23$, NS) (Furness *et al.*, 1985). In Oxford, the correlation between the male unemployment rate and the male parasuicide rate over the period 1976–82 was negative, though not significant ($r = -0.69$) (Hawton, personal communication.)

Discussion

The ecological studies provide somewhat contradictory results. The correlation between parasuicide and unemployment rates across geographical areas is positive, if not always significant, and is markedly reduced when controls for the level of poverty and the psychotropic prescription rate are introduced. Data from Hartlepool and Oxford show that there was no temporal relationship between parasuicide and unemployment from the mid-1970s onwards. In Edinburgh the correlation was found to be positive until 1982, when the parasuicide rate declined precipitately while the unemployment rate continued to rise. This reversed pattern, maintained in 1983 and 1984, might have been anticipated on theoretical grounds: as economic recession worsens, the stigma associated with unemployment would be expected to be less marked, unemployed people would be more integrated in the social order, and their parasuicide potential would decrease. Each unit increase in unemployment above a certain level would be likely to bring about a smaller unit change in parasuicide. When mass unemployment becomes endemic, the change might indeed become negative (such a polynomial equation has been shown by Stack (1981) to fit the relationship between divorce and suicide.

Other explanations of the recent fall in parasuicide incidence include a reduction in the number of prescriptions for hypnotics and tranquillisers (Brewer & Farmer, 1985), a decline in *per capita* alcohol consumption, and a change in cultural attitudes to parasuicide. We also have to consider the suggestion that the fall in the hospital-treated parasuicide rate may be an artefact of changes in medical approaches to the treatment of parasuicide. There is a growing belief among researchers in the field that a smaller proportion of parasuicides are admitted to hospital than formerly. However, there are no empirical data to test this possibility.

The individual-level studies produce more consistent findings and clearer evidence of an association between unemployment and parasuicide. Parasuicide rates among the unemployed are markedly higher than those among the employed, the relative risk rarely dropping below 10 in the Edinburgh series. Relative risk remains significantly high after con-

trolling for social class, age and area of residence. While the impact of recent job loss has been shown to be quite marked, the highest rates (and risks) are found among the long-term unemployed. Finally, the attributable risk analysis shows that over 50% of the overall parasuicide rate may be attributable to unemployment in recent years.

The epidemiological analyses highlight an inverse relationship between the rate of parasuicide among the unemployed (and relative risk) and the prevailing unemployment rate. To account for these findings, Platt & Kreitman (1985a) speculate that the unemployed individual considers himself less socially stigmatised and personally deviant in social situations or contexts of high unemployment than in situations of low unemployment. Consequently, the psychological impact of unemployment may be significantly less marked in high rate unemployment areas, in years of economic recession, and in age groups and social classes where unemployment is a relatively common experience. Discussing the negative temporal relationship between changes in the parasuicide rate among the unemployed and changes in the unemployment rate, Platt & Kreitman (1985a) also suggest that the high rates in the earlier years may reflect a marked degree of psychological and social impairment among those comparatively few individuals who remain unemployed in times of full employment. The decline in the parasuicide rate over subsequent years probably signals the dilution of the 'unemployable' group by others whose status is decreasingly a consequence of personal handicap and increasingly the outcome of impersonal, economic factors.

Platt & Kreitman (1985a) conclude that their findings "are entirely compatible with the hypothesis that unemployment is a cause of parasuicide", although they explicitly recognise that "parasuicide results from the complex interaction of many factors". Their conclusion has been questioned by Shapiro & Parry (1985) and by Hawton & Rose (1986). Shapiro & Parry claim that their finding, that unemployed parasuicides rarely mention unemployment as an important or secondary current problem, gives "no support to the suggestion that those who commit parasuicide see unemployment as being relevant to their action". They go on to warn of the danger of interpreting the higher risk of parasuicide among the unemployed as evidence of a "casual connection". In reply, Platt & Kreitman (1985b) point out that they nowhere suggest that unemployment is a *precipitant* of parasuicide. Indeed, given the finding that parasuicide risk increases with greater durations of unemployment, it would make no sense logically to do so. However, prolonged unemployment may be

a significant *predisposing* factor in suicidal behaviour because it leads to an increase in family tensions, arguments and violence; more depression and hopelessness; increasingly isolation from others; changes in role structure within the family; financial hardship and material deprivation; loss of self-esteem and self-confidence; feelings of reduced self-worth; or any combination of these sequelae. A provoking agent (e.g. argument with spouse) would be more likely to lead to parasuicide in the presence of unemployment (and its associated behavioural correlates) than in its absence (Platt, 1984). Economic recession may also have an indirect effect on psychological well-being and parasuicide by increasingly labour market marginalisation. Those in work are subjected to higher levels of stress, e.g. by enforcing pay restraint, reducing job insecurity and demanding higher productivity. Individuals who in times of full employment are only partially integrated into the workforce and tend to move in and out of work on a regular basis (the subemployed) may find that the opportunities for this lifestyle are severely limited during times of economic instability. Among male parasuicides admitted to the RPTC the subemployed, previously constituting about a quarter of the total, now account for less than 10%. Virtually all of the 'missing' group will have joined the ranks of the long-term unemployed.

In their discussion of the research evidence from Oxford and Edinburgh, Hawton & Rose (1986) consider the possibility of an indirect causal link whereby unemployment may "precipitate or exacerbate factors known to increase the risk of suicidal behaviour, such as social and interpersonal difficulties, poverty and psychiatric disorders". The findings of a higher prevalence of psychiatric treatment and alcoholism among the unemployed

and higher risks of parasuicide in the long-term unemployed would be predicted by such an indirect causal link. However, the findings are also compatible with another type of explanation: that both unemployment and parasuicide are causally related to a third factor. Hawton & Rose postulate that the psychologically vulnerable may be more likely to become and remain unemployed, particularly during a recession, and to engage in self-harmful behaviour. The long-term unemployed may be most at risk of parasuicide because people with psychological vulnerability are over-represented in this group, rather than as a result of the unemployment experience itself. In their conclusion, Hawton & Rose state firmly that we are not currently in any position to decide between these two types of explanation and urge more research on this topic. Clearly their plea deserves to be heard, for both scientific and practical reasons. There are still many areas of ignorance which require illumination, including the link between unemployment and parasuicide among women, the mechanisms by which prolonged unemployment may raise the risk of parasuicide in marginal subgroups, the importance of hopelessness as an intervening social-psychological variable, the temporal relationship between onset of personal difficulties and unemployment among parasuicides, and the role of personality disorder as a possible common link between the two variables. In the meantime, however, we are faced with incontrovertible evidence that the long-term unemployed suffer an unacceptably high risk of parasuicide and that the overall level of parasuicide could be reduced even more if there were a return to fuller employment. Further research is unlikely to alter these facts and their obvious implications for national social and economic policy.

Genetics of Fear and Anxiety Disorders*

I. M. MARKS

From protozoa to mammals, organisms have been selectively bred for genetic differences in defensive behaviour which are accompanied by differences in brain and other biological functions. Studies of twins indicate some genetic control of normal human fear from infancy onwards, of anxiety as a symptom and as a syndrome, and of phobic and obsessive-compulsive phenomena. Anxiety disorders are more common among the relatives of affected probands than of controls, especially among female and first-degree relatives; alcoholism and secondary depression may also be over-represented. Familial influences have been found for panic disorder, agoraphobia, and obsessive-compulsive problems. Panic disorder in depressed probands increases the risk to their relatives of phobia as well as of panic disorder, major depression, and alcoholism. The strongest family history of all anxiety disorders is seen in blood-injury phobia; even though it can be successfully treated by exposure, its roots may lie in a genetically determined specific autonomic susceptibility. Some genetic effects can be modified by environmental means.

Defensive patterns vary greatly among species (e.g. rabbits are more timid than humans) and among individuals within species (some people are more timid than others). The range of stimuli which a species fears, and its defensive response patterns to those stimuli, reflect natural selection of genotypes over the generations and cultural transmission among members of that species. If a category of predators drops out, so do the defences of their prey against them. For example on the Galapagos Islands, where predatory mammals are lacking, hawks, marine iguanas and penguins allow themselves to be touched by humans when they are on land, but in the water the iguanas and penguins are threatened by sharks and flee from a swimming man (Eibl-Eibesfeldt, 1970). Decades of contact with man have not greatly increased these species' defensive behaviour, which presumably derives largely from genetic make-up. Where predators have long been present, animals have been selected for their ability to show and learn defensive behaviour and to transmit it to one another.

Individuals within a species vary in their degree of fear of particular stimuli as a function of their individual genetic make-up and the environment in which it is expressed. The product is a phenotype which describes what is, not what could be. As Plomin & Rowe (1979) state, "even if most of the extant phenotypic differences for a particular trait

were determined by genetic differences, that does not mean that the trait is immutable environmentally".

Other sources of variation within individuals are due to age (each species being more fearful at certain ages than at others), to natural selection of particular fear stimuli into a species' repertoire (prepotent stimuli and prepared associations), and to the cultural transmission and individual learning of fear. This review will concentrate on individual variation within humans in genetic predispositions to fear—the raw material on which natural selection acts. Other species are dealt with in more detail elsewhere (Marks, 1986).

Fear and anxiety are not unitary features but assemblies of numerous characteristics that relate variably to one another; they have many different meanings for the behavioural geneticist. In animals, fear and anxiety have been called 'emotionality' (referring to exploratory behaviour or defaecation scores), 'avoidance conditioning', 'freezing', or 'startle'. In humans, the terms have been equated with changes in skin conductance or heart rate, measures of vigilance, self or observer ratings of fear, worry, or autonomic symptoms in the present (state) or over some enduring period (trait), or with criteria for various anxiety syndromes. Whatever the criterion for fear or anxiety, numerous experiments have demonstrated genetic influences on them in animals and humans.

Each species has characteristic patterns of fear behaviour, which vary slightly among individual members of that species. It is not yet known whether genetic control is on a finite number of discrete basic

Adapted from Chapter 6 of *Fears, Phobias and Rituals*, by Isaac Marks. Published by Oxford University Press, New York, 1986

behavioural units of which those action patterns are composed, or is continuous, although the former seems more probable. Whichever the case, there must be "many pathways, each with its own set of detours, from a locus on a strand of DNA to behaviour" (Carey & Gottesman, 1982). The pathways are especially confusing, firstly because many genes are pleiotropic (each gene affects more than one trait), secondly, because variation in any trait is affected by many genes interacting with each other as part of the genotypic system, and thirdly, because the expression of those genes is variable, leading to more than one phenotypic manifestation of any trait. The goal is to link a gene and its biochemical product with its consequences in the ontogeny of the nervous system and resultant neural function and behaviour.

Defensive behaviour develops out of a complex interaction of multiple genes that takes place in the embryonic and subsequent environment. A hint of a strand in that interaction comes from work on the human pro-opiomelanocortin (POMC) gene, which codes for several polypeptide hormones (Whitfield *et al.*, 1982). POMC is processed in the pituitary into adrenocorticotrophic hormone and other hormones that affect defensive behaviour. The pattern of similarity of POMC protein among different species is reflected in the nucleotide sequence of the coding regions of the gene.

Studies in Non-human Species

Protozoa and Invertebrates

Although genetic variation in normal and abnormal fear in mammals is mostly produced by combinations of genes interacting with each other, for the most part in non-additive fashion, some understanding of components in these interactions may be obtained from single-gene analysis of defensive reactions in unicellular organisms and invertebrates (Fuller & Thompson, 1978; Gould, 1982). At least 20 single-gene mutations are known in the pathways mediating avoidance in *E. coli*, and single-gene analysis in *Paramecium* has revealed some of the DNA bases that affect its membrane potential and resultant avoidance behaviour. In the fruitfly *Drosophila*, avoidance learning and habituation are affected by different types of mutation. In a mutant form called *dunce*, twin failures to learn to avoid and to habituate to stimuli occur with a single genetic defect. This results in the lack of one of the two enzymes which metabolise cyclic adenocine monophosphate, postulated by Kandell (1979) as central for habituation in the sea snail *Aplysia*.

Genes can modify escape behaviour by preventing the normal stimulation required during sensitive

phases for the neural substrate of escape to develop. If that stimulation is not experienced at the appropriate developmental period, then the brain will fail to respond to it later, and can thus affect escape. Unusual predominance of one class of stimuli during the sensitive period can permanently destroy or attenuate responses to others; this may result from competition among incoming cells for synaptic space on the target cells in the cortex. A genetic effect of this kind was shown in mutant crickets that lacked sensory hairs on their vibration-sensitive cercus in the tail; such crickets failed to develop normal escape responses. The same defect in defensive behaviour could be produced in normal crickets by non-genetic means, namely by waxing the hairs (Gould, 1982; Bentley, 1975).

Selective breeding of mammals

Most forms of behaviour can be enhanced or reduced over generations by appropriate selective breeding. The number of generations needed to produce a strain with the desired features depends upon their degree of heritability. In these experiments, man replaces nature as the architect by choosing individuals with particular characteristics and mating them together, to the exclusion of other members of the species who show these characteristics less. Animals have thus been bred for tonic immobility (Gallup & Maser, 1977), for emotionality, and for conditioning of active and passive avoidance, escape, and heart rate (Fuller & Thompson, 1978; Plomin *et al.*, 1980).

In well-known breeding experiments, rodents were reared with companions in a cage and then placed, one at a time, in an unaccustomedly wide, brightly-lit arena (open field), upon which the rodent defaecated, urinated, and explored. This behaviour was taken to indicate 'emotionality' or 'reactivity', and high and low scorers can each be selectively bred. Selection soon yields two strains – reactive and non-reactive – and these have been maintained to the 60th generation of selection in rats (Broadhurst, 1975). The two strains differ on numerous measures of emotionality and learning. Non-reactive rats are also more liable to seizures (Gray, 1979), and have more benzodiazepine receptor binding sites in the brain (Robertson *et al.*, 1978). Controlled experiments showed that the differences in defensive behaviour are genetic, and not due to the pre-natal or post-natal environment.

In another experiment, mice were selected for open-field activity (Plomin *et al.*, 1980; DeFries *et al.*, 1978). Over 30 generations, a 30-fold difference developed between the high and low lines, the low-active strain nearly reaching the bottom limit, and

the high line running the distance of a football field during two three-minute test periods. Although the mice were selected for open-field activity, their defaecation rates in the open field also diverged seven-fold. Open-field inactivity and defaecation correlated (0.80), suggesting that they are influenced by many of the same genes. Heritability was moderately low.

Mice have also been selectively bred for active avoidance, scores for shuttlebox avoidance learning in different strains ranging from near zero to 50% or more. Such inbred lines are useful experimentally, as they yield less variable results than does random-bred heterogeneous stock (Plomin *et al.*, 1980). The mouse strains differ not only in learning to avoid, but also in learning to run through a maze to obtain food. Rat strains have been similarly bred to show 14-fold differences in escape-avoidance conditioning (Broadhurst, 1981).

Pointer dogs, too, have been selectively bred into two separate strains, one excessively fearful, the other reasonably stable (Dykman *et al.*, 1965, 1969). By the second specially bred generation, excessively fearful behaviour was shown by 90% of one strain and stable behaviour by 80% of the other; a visitor would cause the timid pointers to hide and freeze, and the others to approach wagging their tails. Timid dogs showed many additional differences in defensive behaviour. Given the association of freezing with bradycardia (Marks, 1986), it is noteworthy that in timid dogs, which froze often, the heart rate was low from birth onwards, averaging 80 bpm and not varying with petting, nor declining much even after extensive handling; in stable dogs it averaged 120 bpm and declined during petting. Hippocampal theta activity (trains of relatively high voltage waves at 4–8 Hz) were absent in alert timid dogs (Lucas *et al.*, 1974), which is interesting given that in normal dogs, hippocampal theta activity reduces with orienting and avoiding, and returns as they habituate to a situation.

Since the pointers' environments were constant, the differences between strains were best accounted for by genetic factors, the mode of inheritance probably being polygenic. Behaviour of the timid and the stable dogs did not differ when they were in their home cages and in the absence of human or novel stimuli. Maturation was important, activity scores and freezing time to noise becoming typical by the age of three or four months.

The development of five breeds of dog and their hybrids was studied over two decades (Scott & Fuller, 1965; Fuller & Thompson, 1978): within breeds, there was substantial genetic variability in defensive behaviour. Such behaviour also differed markedly between breeds, varying with age, and actually being accentuated rather than attenuated by

life experiences. Most of the strain differences in emotional reactions seemed situation-specific, e.g. basenjis were more afraid of strange apparatus than of other dogs. Selection for confidence in one situation did not necessarily affect timidity in another; unwanted timidity occurred in almost every breed, its very universality suggesting that it is necessary for existence.

Other differences in defensive behaviour among various breeds of dogs were noted in passive-defensiveness, this being increased further in all breeds by rearing in a kennel rather than in a home (Krushinskii, 1966). Others found contrasts between dog breeds in persistently raised heart and respiration rate, salivation, high energy metabolism and urinary catecholamines, and vasopressin release (Corson, 1977; Corson & Corson, 1983).

Tonic immobility is another defensive behaviour under genetic influence (Gallup & Maser, 1977). Even after rearing under identical conditions, after only one generation chickens derived from parents that had long reactions remained immobile four times longer than chicks from parents that exhibited brief immobility. Similar strain differences and effects of selective breeding were reported for tonic immobility in rats (McGraw & Klemm, 1973).

Very little research has examined the genetics of fear in primates. In rhesus monkeys there may be some genetic influence, since heart rate deceleration and cortisol response to challenge in the first month of life, which predict fearfulness, separation anxiety and depression over the next three years, were more similar among sibs and half-sibs than among unrelated monkeys, even though they were reared together under similar conditions (Suomi, 1983).

Work in Humans

Normal fear and anxiety

As in animal research, different aspects of human defensive behaviour show considerable specificity. The various tests of fear and anxiety (e.g. the numerous measures of 'neuroticism') are only grouped together to convey a broad view of the many indicators of negative emotional states that have been examined. It is not meant to imply that they denote a unitary dimension, still less that there must be continuity between normal fear and syndromes of morbid anxiety.

Siblings differ from birth onwards in the intensity of their startle response and fears (Valentine, 1930). Over the first year of life, the development of smiling and of fear of strangers was more similar among monozygotic (MZ) than among dizygotic (DZ) twins (Freedman, 1965). At the age of about 22 months, in

interaction with a stranger but not with the mother, the degree of apprehension was more similar among MZ than among DZ twins (Plomin & Rowe, 1979). Slightly older twins, aged about 3.6 years, showed a substantial genetic influence on their emotionality (Plomin & Rowe, 1977). In school-aged twins, with a mean age of 7.6 years, emotionality, tension, and shyness were significantly more similar among MZ and DZ twins (O'Connor *et al.*, 1980). At the age of seven, MZ twins significantly more concordant than DZ twins for separation distress, emotional reactivity, and being fearful and inhibited (Goldsmith & Gottesman, 1981).

An adult twin series was given a neuroticism questionnaire about emotionality, nervousness, and shyness (Shields, 1962). Again, MZ twins were more similar than DZ twins; moreover, MZ twins reared apart were more similar than were DZ twins reared together. Furthermore, in this and in two other studies (Newman *et al.*, 1937; Juel-Nielsen, 1965, cited by Murray & Reveley, 1981), the degree of resemblance between the MZ twins reared apart was close to that between MZ twins reared together. In contrast, however, among 5000 Finnish twins of whom 167 were reared apart, neuroticism had a lower heritability among those reared apart than together; environmental factors explained at least 60% of the variance in the twins reared apart (Koskenvuo *et al.*, 1983).

Other studies, too, found substantial genetic contributions to personality traits related to timidity (McGuffin & Reich, 1984); this was the case for social introversion in normal adolescent twins (Gottesman, 1963) and for neuroticism in adults (Eysenck & Prell, 1951). Another investigation found that genetic factors contributed about half the variance on all dimensions of personality, judged by the responses of 850 pairs of twins to the California Psychological Inventory (Loehlin & Nichols, 1976). Further twin data with normals have found significant heritability for: being highly-strung, easily upset, and 'a worrier', whether measured by the Minnesota Multidimensional Personality Inventory (MMPI), the Eysenck Personality Inventory (EPI) or the Differential Personality Questionnaire; and for specific forms of this anxiety, e.g. rapid changes in mood, constant worrying, etc. (Carey & Gottesman, 1981).

Physiological responses associated with emotionality are also more alike in MZ than in DZ twins, e.g. habituation of skin conductance responses and their number of spontaneous fluctuations, pulse and respiration rate, blood pressure changes, and EEG variables (Carey & Gottesman, 1981; Lader & Marks, 1971).

Four sets of data concerning self-reported fears in normals and their relatives deserve mention. The first three come from twin studies. In one, a fear survey schedule was administered to 91 MZ and 60 DZ twin pairs and to 66 pairs of parents and their twin offspring (Rose *et al.*, 1981); analysis revealed "consistent evidence of heritable variation". In another study (Rose & Ditto, 1983), responses to a fear survey schedule were examined in 354 pairs of like-sex twins aged between 14 and 34. For all fear factors the co-twin's score and the interaction of co-twin's score with pair zygosity significantly predicted a twin's fearfulness, but the power of this prediction varied among different fears, being twice as great for fear of misfortune in a loved one as for fears of dangerous places. Age also affected the contribution of heritability, fear of death being equally similar among MZ and DZ twins during development, but more similar among MZ and DZ twins by the time they reached maturity.

Based on data from the foregoing two studies, two fear factors (social criticism and leadership) were subjected to critical path analysis in order to separate correlated genetic and cultural effects (Neale & Fulker, 1984). This analysis showed that both fear factors had about equal environment and genetic components, with only a small amount of negative genetic-environmental covariance induced by parental phenotypic influences on their offspring.

In a third investigation (Torgersen, 1979), 99 same-sexed twin pairs (11 of the pairs having one twin as an in-patient for neurosis) were interviewed and given a fear questionnaire. MZ twins were more similar than DZ twins for strength and type of fear, except for separation fears (agoraphobia).

The fourth study (Carey & Gottesman, personal communication) was of 151 families (654 individuals) of psychology students, unselected for the presence or absence of psychopathology. All subjects completed a questionnaire about fears and phobias; ten agoraphobia-like cases were selected, and the prevalence of phobias calculated in their first-degree relatives and in the whole study sample. Compared with the whole sample, the relatives of agoraphobia-like probands had significantly more phobias (any phobia, animal phobia, non-animal phobia, multiple phobias, agoraphobia, and obsessions), fears (animals such as snakes, rats, spiders, and bats, and health and social fears) and orderliness. No difference was found for fears of 'normal' animals (dogs, cats, horses, birds, fish) and of physical situation (heights, storms, water and swimming, doctors, hospitals, and enclosed places). There was thus a familial aggregation of many phobias and fears, although this need not be genetic in origin.

Anxiety syndromes

Undifferentiated anxiety disorders and neurosis

Varying diagnostic labels and methods of study over the years and in different countries make it hard to compare investigations and to work out the heritability of each syndrome recognised today. Data will therefore be included concerning not only phobic and obsessive-compulsive disorders, but also panic disorder, generalised anxiety, and neurosis (Carey, 1982; Gottesman, 1963; Carey & Gottesman, 1981; Murray & Reveley, 1981).

Family and family history studies. Although heritability of a problem requires it to run in families, familial prevalence need not imply heritability. Adoption and twin studies are more conclusive on that issue, but only the latter have been made for neuroses: between 1869 and 1948, at least 19 separate reports noted a familial predisposition to anxiety disorders (Cohen *et al*, 1951). Studies of anxiety disorder were reviewed by Carey (1982) (Table I): except for the most recent studies, samples with 'anxiety neurosis' include an unknown number of cases with agoraphobia and with panic disorder without agoraphobia. Most of the earlier reports were of family history studies in which the proband with anxiety neurosis was interviewed about the presence of the disorder in family members. Fewer cases were likely

to be missed by the family studies, in which all relatives were interviewed directly.

About twice as many cases of anxiety neurosis are found among female as among male relatives (Table I). A similar ratio is found in the study by Cloninger *et al* (1981) if one adds to their low prevalence of definite cases included in Table I the questionable anxiety neurotics blindly diagnosed by the research team (19% of females, 8% of males) (Carey, 1982). This female preponderance among relatives reflects that seen for anxiety neurosis in the general population and in general medical practice, but is greater than that in psychiatric practice (Lader & Marks, 1971).

Table I shows that the prevalence of anxiety disorder among first-degree relatives in family history studies is 15–18%, two to three times more than that in two of the three non-twin family studies (except for that of Cloninger *et al*, 1981). Relatives of anxiety neurotics have a far higher prevalence of the disorder than the available controls. The lifetime risk of anxiety neurosis was 6% among the controls of Wheeler *et al*, (1984) – only one-eighth of the prevalence found in the children of their probands, diagnosed as having 'neurocirculatory asthenia' 20 years previously. Among the relatives of the surgical controls of Noyes *et al* (1978), the risk of anxiety neurosis was 3% – merely one-sixth of that among the

relatives of their probands with anxiety neurosis. In a subset of their sample, the first degree relatives of 41 probands with panic disorder had an age-corrected risk of anxiety disorder of 25%, compared with 2% in first degree relatives of controls (Crowe *et al*, 1983). In the general population, the prevalence of anxiety disorder is about 4% (Lader & Marks, 1971; Weissman *et al*, 1984).

Of a proband's genes, half are shared with first degree relatives and a quarter with second degree relatives. The pooled risk of anxiety disorder is 15% for first degree and 6% for second degree relatives (Table I). However, the correlations in liability (i.e. the degree to which combined genetic and environmental factors are producing anxiety disorder in the relatives of probands when compared with the population prevalence) based on a population prevalence (K_p) of 0.04 suggest that the data could reflect the common environment shared by first degree relatives (McGuffin, personal communication).

The risk to first degree relatives is greatest when both parents have anxiety disorder and least when neither have it (Table II). Prevalence was also higher in relatives of probands with chronic as opposed to acute anxiety neurosis—22% compared with 5% (Cohen *et al*, 1951). Such findings make polygenic-multifactorial inheritance plausible (McGuffin & Reich, 1984). More than genetic factors may be involved, as most studies find that parents of probands have higher rates of illness than do siblings (McGuffin & Reich, 1984). However, this could also come about because siblings have not lived through as long a period of risk as their parents have.

Are other disorders over-represented in the families of anxiety neurotics? Alcoholism may be more common (Noyes *et al*, 1978; Weissman *et al*, 1984),

and children have a greater risk of major depression or phobia if their parent proband has both major depression and either agoraphobia or panic disorder (Weissman *et al*, 1984). The minor congenital cardiac anomaly of mitral valve prolapse (MVP) is more common among anxiety neurotics than among controls (Crowe *et al*, 1981). However, the familial incidence of panic attacks is no higher among probands with MVP than among controls (Crowe *et al*, 1982). A higher familial incidence of panic attacks in the 12 MVP probands who also had panic attacks than in the 38 without them suggests independent segregation of MVP and of panic attacks.

Twin studies. Four twin studies of neurosis, of variable quality, were reviewed by Fuller & Thompson (1978). The concordance rate was 56% for MZ and 40% for DZ twins, excluding the twins reported by Slater & Shields (1969). Much greater differences between MZ and DZ pairs were found in two more series of twins with anxiety neurosis, in which probands were ascertained more systematically (Slater & Shields, 1953; Torgersen, 1978). Starting with one affected twin, concordance rates were respectively 41% and 30% for MZ twins, but only 4% and 9% for DZ twins (Table I); the differences between MZ and DZ twins were significant in both studies. Using the criterion of marked anxiety rather than a diagnosis of anxiety state, the concordance rate for MZ twins rose from 41% to 65% and for DZ twins from 9% to 13% (Slater & Shields, 1969), suggesting a genetic predisposition to anxiety both as a symptom and as a syndrome.

The DZ twin data yield a much lower risk for anxiety disorder (4–9%) than the other studies (15–49%) of first degree relatives. This may partly reflect differing diagnostic criteria. High rates were found among first degree relatives where probands had typical and severe anxiety (DSM-III type panic disorder) (Crowe *et al*, 1983), and lower rates where probands were unselected (Cloninger *et al*, 1981).

Among 229 same-sex neurotic adult twins who received psychiatric treatment, greater concordance of MZ over DZ twins for neurosis was absent in females and present only in twins who were male or had been psychiatric in-patients (Torgersen, 1983). Greater familial tendencies among males than among females have also been found for phobic fears among same-sexed twins (Torgersen, 1983) and for neuroticism on the Maudsley Personality Inventory (MPI) of neurotic in-patients (Coppin *et al*, 1965).

Such sex differences might be explained by cultural variables such as sex-role stereotypes pressuring women more than men; men may show the disorder only when the genetic loading is high (Reich *et al*, 1972).

2 Panic disorder only

Defined anxiety syndromes

Broad diagnostic labels such as 'neurosis' or 'anxiety' overlap in variable degree with reports of more detailed diagnostic categories, discussed below.

Panic disorder. A pedigree analysis of the relatives of 19 probands with panic disorder suggested that the disorder is familial (Pauls *et al*, 1980). The same was found in a larger study from the same centre, of the relatives of 41 probands with panic disorder, of whom 11 also had agoraphobia as a diagnosis and a further 11 had it as a symptom (Crowe *et al*, 1983); controls were matched by hospital personnel for age and sex. The lifetime morbidity risk of definite plus probable panic disorder for first degree relatives of panic disorder probands was 25% (33% for women, 17% for men), compared with 2% for relatives of controls ($P < 0.001$), corresponding figures for definite panic disorder alone being 17% and 2% respectively. Either definite or probable panic disorder was found in at least one first degree relative in 61% of panic disorder probands, compared with only 10% in control families ($P < 0.001$). Probands' relatives had an excess of generalised anxiety disorder or primary depression, and only a trend to more alcoholism, although secondary depression was increased (16% versus 7%). Of interviewed relatives of panic disorder probands, 55% had received treatment for their anxiety; in 14% this was psychiatric treatment. Crowe *et al* thought that this evidence was compatible with both multifactorial and single gene models.

Relatives of 77 probands who had major depression plus panic disorder were compared with those of probands who had major depression without any anxiety disorder (Leckman *et al*, 1983). Relatives of the former had more than twice the risk of major

depression, panic disorder, phobia, and alcoholism.

Phobic disorders. Most family data have concerned agoraphobia and one type of specific (simple) phobia – that of blood and injury. Very little has been reported about other specific phobias, social phobia, or illness phobia.

Agoraphobia has been examined systematically: a high familial prevalence of anxiety, phobic and depressive disorders and sometimes alcoholism has usually been found (Tables III and IV). An exception was the study of Buglass *et al* (1977); among the relatives of agoraphobic women they found little familial prevalence compared with normal controls, apart from an increase in non-phobic psychiatric disorders among brothers (17%). Most other workers reported increased familial morbidity. A high rate of phobic disorders was found among mothers (31%), along with an increase in other neuroses among both parents (55% of mothers, 24% of fathers) (Solyom *et al*, 1974), and a higher than expected rate of school phobia among the children (14% for ages 11 to 15) (Berg, 1976). More neurosis was noted in the families of agoraphobics (33%) than of temporal lobe epileptics (Harper & Roth, 1962). Increased family histories of depression and of alcoholism were noted among the relatives of agoraphobics, compared with those of social and simple phobics (Munjack & Moss, 1981).

In a family study of agoraphobia, panic disorder, and non-anxious controls (20 probands per group), the morbidity risk for all anxiety disorders among first degree relatives was respectively 32%, 33%, and 15%, the risk for relatives of controls being lower (Harris *et al*, 1983). Risk of anxiety disorder was increased by more than twice among female relatives of ill probands, while male relatives of agoraphobics were also at higher risk for alcoholism. Relatives of agoraphobics were at increased risk not only for

agoraphobia, but also for panic disorder and for other phobias, while those of panic disorder only had a raised risk of panic disorder. Major depression and other psychiatric disorders were not increased in the relatives of ill probands. The increased rate of alcoholism in families of agoraphobics accords with the findings above (Munjack & Moss, 1981) and with those in anxiety neurotics (Cohen *et al*, 1951; Noyes *et al*, 1978; Crowe *et al*, 1980).

In another study, the familial risk of agoraphobia was ascertained by questionnaire and interview data from 60 agoraphobic probands (52 women, 8 men) (Moran & Andrews, 1985). Among all parents and siblings, the risk of current or past agoraphobia was 12½%; the risk was twice as great among female relatives. Proband tended to have either a parent or a sibling affected, not both; the risk to parents was not less than that to children, contrary to what would be expected with transmission from a single recessive gene. Direct transmission through three generations, which is usually regarded as a feature of dominant inheritance, was reported in only two families. The overall risk was greater than the estimates of population incidence of agoraphobia in the Epidemiological Catchment Area study in New Haven, St Louis and Baltimore of 4.1%; correlation in liability was on the low side (0.26 to 0.46), depending on the sex of proband and of first-degree relatives.

Why agoraphobia runs in families, and especially among female relatives, remains unclear. The higher risk among female relatives could reflect cultural differences in the mode of expression of agoraphobia. Men might experience similar panic but show less avoidance and be more likely to drink alcohol—as we saw, the risk of alcoholism is raised among the male relatives of agoraphobics, and the female preponderance is distinctly less in anxiety states (panic disorder without agoraphobia). In obsessive-compulsive disorder, too, fewer men have washing rituals in which avoidance of dirt is prominent, but more men have checking rituals in which avoidance is less obvious (Marks, 1986).

The familial prevalence of agoraphobia is unlikely to result solely from modelling within the family (Moran & Andrews, 1985). Many of the agoraphobic probands had never heard of agoraphobia, let alone met a sufferer. Of the probands, 85% came from a family in which neither parent was reported to be agoraphobic.

In another family study of anxiety disorders (Cloninger *et al*, 1981), the greatest familial prevalence of anxiety neurosis was among the kin of six probands who had severe chronic agoraphobia. Among twins with panic disorder or agoraphobia

with panic attacks, anxiety disorders were more than five times as frequent in MZ as in DZ co-twins (Torgersen, 1983). The degree of similarity of the twins' childhood environment did not affect the degree of concordance within the MZ or DZ groups.

Blood-injury phobias have the strongest family history of all the various forms of anxiety disorder (Marks, 1986). Unlike most other phobias, the majority of blood-injury phobics report other family members with a similar problem (Connolly *et al.*, 1976; Marks, 1981; Yule & Fernando, 1980). Among blood-injury phobics, fully 68% had biological relatives who were blood phobic, a rate three to six times higher than the frequency of corresponding phobias among the relatives of agoraphobias or social, dental, or animal phobics (Mark, 1969; Marks & Herst, 1970; Öst *et al.*, 1984; Öst & Hugdahl, 1985). The concordance of blood-injury-illness phobias was higher among MZ than among DZ twins.

This strong family history suggests that blood-injury phobias may originate in a genetically-determined extreme autonomic response. Unlike the tachycardia which is the usual response of most phobics on encountering their phobic stimuli, the cardiovascular response of blood-injury phobics to their phobic stimuli is biphasic, consisting of initial tachycardia followed by profound bradycardia, even to the point of asystole and fainting (Marks, 1986). The degree of bradycardic response of blood-injury may be normally distributed in the general population for genetic reasons (just as are height, intelligence, and many other features that are polygenetically influenced). Presumably only those who have an extreme bradycardic response faint readily, and are thus liable to develop the phobia. This would yield a blood-phobic population with a strong family history, as is found. The bradycardic response is probably present from an early age, as blood-injury phobias start selectively in childhood rather than later (Marks, 1986). It remains to be demonstrated that relatives not only faint frequently, but also have an extreme bradycardic response to blood-injury stimuli.

Perhaps other phobias, too, may partly arise from other autonomic specificities under genetic or environmental influence. For example, when anxious, those with labile blood flow in the cheeks might blush more readily than others, and so be liable to become phobic about blushing; those with undue gastric motility might, when anxious, vomit easily after eating and thus be prone to develop a phobia about that. In addition, blushing may be an autonomic response specifically tied to social cues in the same way that bradycardia with fainting seems linked to blood-injury stimuli, so that blushers

would become phobic of social rather than of other situations.

Cary (1982) investigated 21 twin probands with phobic disorders; of these, seven of the eight MZ co-twins had either a phobic disorder or phobic features, compared with only five of the thirteen DZ co-twins. Several observations argued for a genetic rather than a modelling effect. Firstly, even twins raised apart were concordant. Secondly, in at least two of the concordant MZ pairs the type of phobia present in the one twin was unknown to the other. Thirdly, in one pair of female identical twins, both twins broke down while they were apart in different countries. Fourthly, several pairs were concordant in having agoraphobia-like features, but discordant in the details of the particular stimuli which they feared (e.g. darkness and enclosed places for one, leaving the house alone for the other).

The MMPI on these and obsessive-compulsive twins also suggested genetic effects (Carey & Gottesman, 1981). The mean profile reflected a dysthymic personality, with much tension, obsessive-compulsive worry, feelings of personal inadequacy, and autonomic symptoms of anxiety. This profile suggested someone quiet, seclusive, conventional, anergic, sensitive, and socially submissive. Profiles from MZ co-twins paralleled those for probands, but were less extreme. A similar but less marked profile was seen in DZ co-twins, but lacked a peak on the psychasthenia scale.

Further evidence of the heritability of phobias comes from the MMPI of 26 twins, reared apart on average from the age of four months to 24 years. The intra-class correlations were 0.50 for phobias and, on clinical scales, 0.52 for psychasthenia and 0.56 for A (Welsh) (Gottesman *et al.*, 1982). (An intra-class correlation compares variability within twin pairs with that between twin pairs; implications of genetic effects are strong with values of 0.6 to 1.0, and moderate to weak with values of 0.3 or less).

Obsessive-compulsive disorders. (Murray & Reveley, 1981; McGuffin & Reich, 1984).

Excluding the atypical report of Lewis (1935), some psychiatric abnormality was found in a high proportion of relatives: 40 to 50% of parents and 19 to 39% of siblings (Table V), and 16% of children (Carey, 1978). Obsessive-compulsive illness was found in 2 to 10% of parents and sibs (Table IV), and in a lower proportion (but still eight times more than in the general population) by Rosenberg (1967). Responses of 404 normal twin pairs to the Leyton Obsessional Inventory indicated that the hereditary proportion of the variance was 44% for obsessive traits and 47% for obsessive symptoms (Murray *et al.*, 1981).

TABLE V
Percentage of disorder in first-degree relatives of obsessive-compulsive patients¹

Study	Obsessive-compulsive disorder		Obsessive-compulsive personality		Any noteworthy psychiatric condition	
	Parents	Sibs	Parents	Sibs	Parents	Sibs
Lewis (1935)	37	20	18	10		76
Brown (1942)	7	7	33	20	50	36
Rudin (1953)	5	2	3	3	40	19
Kringlen (1965)		10				
Carey (1978)		5	14		48	39

1. From McGuffin & Reich (1984)

Among obsessive twins, Carey (1978) found reports of 30 concordant and 13 discordant MZ pairs, and of no concordant but 14 discordant DZ pairs; this could reflect a tendency to report concordant pairs more often. Interesting discordance was found in identical triplets who all became psychotic, but only one of whom developed obsessive-compulsive disorder as well (subsequent to the report) (McGuffin *et al*, 1982). The largest twin series (15 MZ, 15 DZ) is that systematically investigated by Carey (1982). Obsessive symptoms or features were found in 87% of MZ and 47% of DZ twin pairs.

Discussion

Genotypic variation contributes to differences in defensive patterns among individuals within a species. Genetic influences on a trait need not mean that it cannot be altered by environmental effects: its phenotypic expression depends on the surroundings in which the individual develops. Potential paths from genes to defensive behaviour are hinted at by single-gene analysis of avoidance and escape behaviour in invertebrates; how genes interact together and with environmental factors to result in defensive responses in vertebrates is still unknown.

Animals have been selectively bred for many types of defensive behaviour. Genetic differences in defensive behaviour have been found to be accompanied by differences in the number of benzodiazepine receptors in the brain, hippocampal theta activity, in heart, respiration and salivation rates, and in energy metabolism, cortisol response to challenge, urinary catecholamines, and vasopressin release.

Normal human fear is partly under genetic control from infancy onwards. Compared with fraternal (DZ) twins, identical (MZ) twins are more similar as infants in their fear of strangers, and as children

and adults on measures of emotionality, emotional lability, neuroticism, shyness, social introversion, worry, tension and fears, and on physiological variables such as pulse and respiration rate, blood pressure, EEG, and skin conductance.

Among the relatives of probands with anxiety disorders, such problems are far more common than in control families. Twice as many cases are present among female than among male relatives, and among first than among second-degree relatives. The more parents that have anxiety disorder, the greater the risk to first-degree relatives. Alcoholism and secondary depression may also be over-represented among relatives. Twin studies also suggest a genetic predisposition to anxiety both as a symptom and as a syndrome; this may be less evident in women than in men, as sex-role stereotyping may lead women to display fear and anxiety more readily.

Using more refined diagnostic categories, the highest familial incidence of all is in blood-injury phobia, which may originate in a genetically influenced autonomic vulnerability from childhood onwards to have bradycardia and faint at blood-injury stimuli. Familial and genetic influences are also evident in panic disorder, agoraphobia, and phobic disorders as a whole. The presence of panic disorder in depressed probands increases the risk to their relatives of major depression, panic disorder, phobia, and alcoholism; MZ twins are more concordant than DZ twins for phobias and on MMPI profile. Internal evidence from agoraphobia and from phobias as a whole argues for a genetic rather than a direct modelling effect, although other cultural factors presumably interact with genetic ones. Obsessive-compulsive problems are far more common among the relatives of obsessive-compulsive probands than in the general population, and more concordant MZ than DZ twin pairs have been reported.

Conclusion

There is some evidence for genetic effects on normal fear and anxiety, on anxiety disorders as a whole, and on panic and obsessive-compulsive disorders, agoraphobia, and blood-injury phobia. Apart from the possible origin of blood-injury phobia in a specific autonomic susceptibility, little is known about how these genetic factors might operate, about potential biological markers for them, or about how they might be modified by environmental means.

Exposure therapy produces rapid and lasting improvement in blood-injury and other phobias and in compulsive ritualisers, even when they have a strong family history; whether this fact can lead to useful preventive principles in bringing up genetically vulnerable individuals is worth exploring.

The Continuum of Psychosis and its Implication for the Structure of the Gene

T J. CROW

Three observations challenge Kraepelin's binary view of the functional psychoses: a bimodal distribution of the clinical features of manic-depressive illness and schizophrenia has not been demonstrated; affective illness appears to predispose to schizophrenia in later generations; and 'schizoaffective' illnesses cannot be separated in family studies from either of the prototypical psychoses. The alternative concept is that psychosis is a continuum extending from unipolar, through bipolar affective illness and schizoaffective psychosis, to typical schizophrenia, with increasing degrees of defect. According to this concept the genes predisposing to psychosis have a degree of stability that ensures that the form of the psychosis tends to remain the same within families, but there is also the possibility of change, implying that the genetic mechanisms themselves are variable. It is proposed that quantal changes in the 'virogene' are due to replications within the genome (e.g. the generation of tandem repeats of the element or a component of it); that such replications occur at a critical stage (e.g. gametogenesis, fertilisation, very early embryogenesis) in the course of reproduction; and that the 'season of birth effect' reflects the operation of the mechanism responsible for these replications.

Contemporary classifications of psychiatric disease owe much to Kraepelin (1899). At the end of the last century he distinguished the organic from the functional psychoses¹ and, in the latter category, separated manic-depressive insanity from dementia praecox (schizophrenia). The separation was achieved on the basis of outcome—an episodic course with recovery from individual episodes was regarded as characteristic of manic-depressive illness, while in dementia praecox an element of persistence and even progression was to be expected. Although exceptions are recognised, this generalisation on outcome has survived relatively unchallenged.

Kraepelin's 'binary' view has dominated subsequent work to the extent that the entities of schizophrenia and manic-depressive illness are widely regarded as separate diseases, each with a different genetic background, treatment and outcome (Gershon & Rieder, 1980; Loranger, 1981). The earlier view (Guislain, 1833; Neumann, 1859; Griesinger, 1861) that there is a unity in the psychoses (the 'einheit-psychose') has yielded to common observation that typical cases of manic-depressive illness and schizophrenia have distinct psychopathological features, usually follow their predicted courses, and are associated with an incidence of similar illnesses in first degree relatives.

This paper presents an alternative to Kraepelin's

binary concept. Doubts about the binary hypothesis arise firstly from the failure of Kendell and co-workers (Kendell & Gourlay, 1970; Kendell & Brockington, 1980) to achieve a bimodal separation of the two conditions on the basis of symptoms or outcome. Secondly, the similarity of season of birth and season of onset effects suggests that the psychoses share aetiological determinants. Thirdly, in family studies two findings indicate that the conditions are more closely related genetically than is generally believed: several investigations have shown an excess of children with schizophrenia among the offspring of parents with affective disorder, and studies of 'schizoaffective psychosis' have failed to separate this entity from either affective disorder or schizophrenia.

The alternative concept is that there is a continuum of psychosis extending from pure affective disorder to schizophrenia with the defect state. The existence of such a continuum would imply that the genetic mechanisms postulated to underlie it are subject to more rapid change than is associated with most human genes.

Limitations of the binary concept

A persistent problem for the binary view has been the undoubted occurrence of psychoses with both manic-

depressive and schizophrenic symptoms. Kasanin (1933) introduced the concept of 'schizoaffective psychosis' and initiated discussion as to whether such illnesses are variants of one or other of the prototypes, or constitute a 'third psychosis'.

It is generally assumed that 'true' schizoaffective psychoses, which cannot be placed in either category, are relatively rare, and that the majority of psychotic illnesses can be classified as either affective or schizophrenic. It would thus be expected that a discriminant function based on the characteristic features would separate the two conditions with relatively few intermediate cases. In testing this prediction on data from the US/UK Diagnostic Project, collected using the Present State Examination and a semi-structured history schedule, Kendell & Gourlay (1970) on the contrary found a distribution with a maximum of cases at the mid-point between the two typical pictures (Fig. 1). A discriminant function which

FIG. 1 The distribution of the weighted scores of 146 patients with schizophrenia and 146 patients with affective disorder from the US-UK study on the discriminant function derived by Kendell & Gourlay to maximise separation of the conditions (redrawn with permission from Kendell & Gourlay, 1970)

included all those items which best distinguished patients with a project diagnosis of affective disorder from those with a diagnosis of schizophrenia did not separate two groups at either end of the distribution.

In further sample ($n=217$) Kendell & Gourlay again failed to demonstrate bimodality—this time the distribution on the discriminant function was uni-modal rather than tri-modal. Such findings cast doubt on the common clinical assumption that most cases of psychosis can be relatively easily classified as either affective or schizophrenic.

Returning to the attack, Kendell & Brockington (1980) developed a method for ascertaining a non-linear relationship between symptomatology and

outcome, but were unable to demonstrate such relationships in samples of 127 unselected psychotic and 105 schizoaffective patients. They wrote: "no firm conclusions can be drawn about the relationship between schizophrenic and affective psychoses, though it has to be noted that yet another attempt to demonstrate discontinuity between them has failed."

The diagnostic boundaries of schizophrenia have for long been debated. Nuclear symptoms (e.g. thoughts experienced as alien or as auditory hallucinations) were advanced by Schneider (1957) as pathognomonic, but they define a restricted range of illnesses, and are not directly related to poor outcome (Bland & Orn, 1980). An alternative strategy adopted in recent research criteria (e.g. the DSM-III criteria (American Psychiatric Association, 1980), and the earlier criteria of Feighner *et al.*, 1972) is to include duration as a defining feature. Such criteria are successful in predicting outcome. Outcome for the schizoaffective psychoses, whether studied before (Hunt & Appel, 1936; Clark & Mallett, 1963) or after (Croughan *et al.*, 1974; Brockington *et al.*, 1980) the introduction of operational criteria, is found to be intermediate between schizophrenia and affective disorder. Thus, although bimodality of outcome has been claimed in one study (Cloninger *et al.*, 1985), experience with schizoaffective illness does not appear to support it.

The two prototypical psychoses share some salient features. Both show a tendency to recur, more striking in the case of manic-depressive psychosis but present also in schizophrenia. Onset before puberty is rare in either case, but the disease can occur at any point in adult life, the mean onset of schizophrenia being earlier (by a decade or more) than affective illness. The lifetime prevalence of both conditions approaches 1%. In neither case have characteristic histopathological changes in the brain been established, although recent neuroradiological (Johnstone *et al.*, 1976) and post-mortem studies (Brown *et al.*, 1986) suggest structural changes (e.g. cerebral ventricular enlargement) which are more marked in schizophrenia. Seasonality of onset and of date of birth have been widely discussed as a lead to the aetiology of schizophrenia; such illnesses are more likely (by about 5–10%) to have an onset in the early summer months than at other times of the year, and patients with these illnesses are more likely to have been born in the winter months (Dalen, 1975). These trends follow the seasons in the north and south hemispheres. Similar effects have been found for manic-depressive illness (Hare & Walter, 1978) (Fig. 2).

Two explanations of the similarity of these findings in affective and schizophrenic psychoses suggest

FIG. 2 Monthly births and admissions for schizophrenia and mania expressed as a percentage of the number expected on the basis of overall numbers of births and admissions for neurosis: points represent three-monthly moving averages (redrawn with permission from Hare and Walter, 1978)

themselves: that a statistical artefact has an influence on both sets of data, or that the conditions share a fundamental relationship to the seasons. Such artefacts as have been suggested have been effectively dismissed (Watson *et al*, 1982; Pulver *et al*, 1983), and

therefore the second possibility must be seriously entertained.

The prophylactic value of medication is established in both conditions—lithium in preventing relapse in affective illness (Davis, 1976), and neuroleptic medication in schizophrenia (Davis, 1975). Although such drug specificity suggests differences in the underlying disease processes, some schizophrenic illnesses respond to lithium (Biederman *et al*, 1979; Delva & Letemendia, 1986), and in addition to their efficacy in mania, neuroleptics may be of value in depression (Hollister *et al*, 1967). Thus no unequivocal demarcation of the functional psychoses can be made on the basis of symptoms, outcome or response to treatment, and the seasonality effects suggest an underlying aetiological unity.

Are schizophrenia and affective psychosis genetically related?

It is widely held that the genetic factors which predispose to the two typical psychoses are unrelated. Thus according to Gershon & Rieder (1980), "evidence from twin and family studies suggests that bipolar manic depressive illness and chronic schizophrenia are distinct entities", and according to Reich *et al* (1982) "the genetic diathesis for affective disorders is independent of that for other psychiatric disorders". Several findings suggest that such conclusions are too dogmatic. Rather, the two conditions appear to be related in a way which reveals something about the genetic mechanisms. Specifically, affective illness in one generation may predispose to schizophrenia in the next.

In a survey of the risk of other psychiatric illness in first-degree relatives of patients with affective disorder, Rosenthal (1970) noted an excess of schizophrenia in children (a mean of 2.3% in 5 studies),

TABLE I
Psychotic offspring of psychotic parents classified by diagnosis

Offspring	Parents	
<i>Penrose (1968)</i>	<i>Affective disorder</i>	<i>Schizophrenia</i>
Affective disorder	232	34
Schizophrenia	205	150
<i>Powell et al (1973)</i>	<i>Manic-depressive psychosis</i>	<i>Schizophrenia</i>
Manic-depressive psychosis	10	0
Schizophrenia	15	9

while the risk in parents and siblings remained within the 0.8% lifetime prevalence for the general population. He asked: "From the genetic point of view, why should schizophrenia have occurred at all in these families?"

Two studies have examined parent-child pairs in which both members suffered from psychosis (Table I). Penrose (1968) identified 621 such pairs in a series of 5456 pairs of relatives with psychiatric disease collected over a period of 18 years in the Ontario Mental Hospitals. Among the ill children of schizophrenic parents a diagnosis of schizophrenia preponderated over affective disorder in a ratio of almost 5:1. Among the children of affectively ill parents the ratio was a little less than 1; schizophrenia was almost as common as affective disorder. In a similar study on the Aberdeen case register Powell *et al* (1973) found schizophrenia in the children of schizophrenic parents and affective illness among the children of parents with affective disorder as expected. However, among the latter they found that for 10 cases of affective disorder, 15 cases of schizophrenia were also present.

These findings suggest an excess of schizophrenia among the children of affectively ill parents²; this seems unlikely to be due to a secular trend toward diagnosing more schizophrenia, or to selective factors (e.g. hospital admission) leading to over-inclusion of patients with schizophrenia, as the two samples were

collected 30 years apart on either side of the Atlantic, one from in-patient records and the other from a case contact register.

In a series of 25 children of two manic-depressive parents, Schulz (1940) reported that 7 suffered from affective illness but 3 suffered from schizophrenia. In applying more restrictive diagnostic criteria to a larger literature, Elsasser (1952) found that of 169 children of two parents with manic-depressive or atypical psychoses (i.e. with schizophrenia excluded), 18 suffered from definite affective illness and 6 from definite schizophrenia.

Pollock & Malzberg (1940) collected family histories of psychosis over three generations. In relatives in preceding generations (parents, grandparents, uncles and aunts) of patients with schizophrenia they found an excess of affective illness: 15 cases of affective illness compared with 11 of schizophrenia (Table II).

Slater (1953) reported similar findings. In his study of twins he recorded psychiatric illness in other relatives, and found the ratio of affective disorder to schizophrenia (4:3) particularly high in the parents of patients with schizophrenia. The corresponding ratio (3:5) for siblings similarly showed more affective disorder than would conventionally be expected (Table II). No excess of schizophrenia was found in the parents or siblings of patients with affective disorder.

TABLE II
Psychotic illness in the preceding generations and siblings of patients with affective disorder or schizophrenia

Relative group	Proband diagnosis	
	Affective disorder	Schizophrenia

TABLE III
Risk of psychosis in the first-degree relatives of probands with schizoaffective illness. percentages of relatives affected

Type of psychosis	Angst et al, 1979 (n=150)	Tsuang et al, 1977 (n=52)	Baron et al, 1982 ¹ (n=50)	
			SA-A	SA-S
Schizophrenia	5.26	0.9	0	4.1
Schizoaffective psychosis	2.97	—	3.2	1.4
Affective psychosis	6.70	11.8	28.1	10.9

1 Schizoaffective illness was subdivided into mainly affective (SA-A) and mainly schizophrenic (SA-S) subtypes

In an earlier study of manic-depressive illness (Slater, 1936) "a surprising feature had been the number of schizophrenics among the children . . . In 10 of the 15 cases where manic-depressive subjects had been found by Dr Slater to have schizophrenic children he had been unable to find schizophrenia in other members of the patient's family or that of the husband or wife".

Each of these observations, therefore, is consistent with a one-way movement between generations from affective disorder to schizophrenia. On the basis of his own family studies Myerson (1925) summarised what he believed to be the inheritance of mental disease: "that the manic-melancholic diseases are in the main followed by manic-melancholic diseases, but in a certain number, especially of doubtful cases by dementia praecox . . . that the manic-depressive states of involution trend toward manic-depressive and dementia praecox, especially the latter . . . that dementia praecox in an ancestor trends toward dementia praecox in the descendants with a certain scattering incidence of imbecility."

Such a notion is an echo of the concept of the degeneration psychosis as formulated by Morel (1860) and Magnan (1893). As a genetic theory it is unorthodox, but on the accumulated literature looked at from an intergenerational standpoint it appears it cannot be easily dismissed.

The genetics of schizoaffective disorder

On account of the historical origins of the concept of schizoaffective psychosis and its pivotal position in nosology, particular interest attaches to the genetics involved.

In the largest study to date, Angst *et al* (1979) found the risk of schizophrenia and affective disorder to be approximately equal in first degree relatives of schizoaffective probands, and that of schizoaffective

illness to be appreciably less than that of either of the prototypical psychoses (Table III). Two other surveys (Tsuang *et al*, 1977; Baron *et al*, 1982) found schizoaffective disorder to be more closely related to affective illness than to schizophrenia. Each group of researchers inferred that schizoaffective illnesses are not genetically separate from the major (particularly affective) psychoses. The conclusion that schizoaffective illness is not a genetic entity was also reached by Tsuang (1979) in a study of pairs of siblings with psychosis. When diagnoses were blindly allocated to the categories of schizophrenia, affective disorder, and schizoaffective disorder, a deficit of schizoaffective $\times$ schizoaffective pairs was observed relative to the number of such diagnoses in the sample. Eight schizoaffective $\times$ affective, five schizoaffective $\times$ schizophrenic, and two schizophrenic $\times$ affective pairs were present in a sample of 35 pairs.

The relationship of schizoaffective illness to the affective disorders is illuminated by Gershon *et al*'s (1982) study with modified Research Diagnostic Criteria of 1254 relatives of patients with major affective disorder: "These data were compatible with the different affective disorders representing thresholds on a continuum of underlying multifactorial vulnerability. In this model schizoaffective illness represents greatest vulnerability, followed by bipolar . . . then unipolar (affective) illness". These authors thus espouse a continuum concept which extends up to schizoaffective illness but excludes schizophrenia.³

If schizoaffective disorder does not breed true and has a relationship (as suggested by Tsuang *et al* (1977), Baron *et al* (1982) and Gershon *et al* (1982)) to affective disorder, the question arises whether an excess of schizoaffective illness (or affective disorder) is seen amongst first degree relatives of patients with schizophrenia when schizophrenia is narrowly defined as in recent operational criteria. Kendler *et al*

TABLE IV

Morbid risk of schizophrenia, affective disorder, schizoaffective disorder and atypical psychosis (determined by DSM-III criteria) in blindly assessed first degree relatives of patients with schizophrenia and surgical controls (from Kendler et al, 1985)

Diagnosis	Relatives affected. %		P
	Schizophrenics (n=332)	Controls (n=318)	
Schizophrenia	3.7	0.2	7.9×10^{-8}
Schizoaffective disorder	1.4	0.1	0.008
Atypical psychosis	2.5	0.3	0.0006
Affective disorder			
Unipolar	6.0	7.6	NS
Bipolar	1.2	0.3	NS

(1985) reanalysed a consecutive series of 510 patients with a chart diagnosis of schizophrenia from the Iowa Hospitals with the DSM-III criteria, and compared rates of illness in the relatives of 332 patients with a DSM-III diagnosis of schizophrenia with those in relatives of 318 surgical controls. In their analysis of personal interview or hospital records these authors found that while the risk of affective disorder was not significantly increased, the risk of schizoaffective disorder and atypical psychosis was (Table IV). Even with a restrictive definition of schizophrenia, therefore, no 'genetically pure' syndrome is isolated, and a relationship with the schizoaffective spectrum remains.⁴

Thus it seems that schizoaffective illness occurs in the relatives of patients with both schizophrenia and affective disorder even when these illnesses are restrictively defined. Unless schizoaffective disorder can be partitioned into schizophrenic and affective types of illness (and since the concept originated in the failure of such an enterprise, this seems unlikely), parsimony requires the conclusion that schizoaffective disorder is but the bridge between affective disorders and schizophrenia.⁵ The psychoses constitute a genetic continuum rather than two unrelated diatheses (Crow & Cooper, 1986).

The genetics of a continuum

However, there is also a degree of stability of clinical picture within families; without this, the Kraepelinian dichotomy could hardly have survived.⁶ Within families (perhaps particularly within generations) the form of the psychosis tends to breed true. Such a trend is accentuated when (as often in genetic studies) cases which do not fit the two classical pictures

are excluded from consideration. A more faithful representation is obtained when the series of cases is unselected and intermediate diagnoses of probands and relatives are allowed. Thus in his series of consecutive admissions with psychosis Ødegaard (1972) included schizophrenic psychoses of three grades of defect, and the categories of schizophrenia without defect, reactive psychosis and atypical affective psychosis cover most of what would be described as schizoaffective illness in other classifications. The incidence and type of illness in relatives (Fig. 3) is

FIG. 3 Relative risks of psychiatric disorder, classified from case histories, in the first and second degree relatives of a consecutive series of admissions of patients with psychosis (data taken from Ødegaard, 1972)

compatible with the concept of a genetic continuum along which conditions are distributed with increasing severity from typical manic-depressive psychosis to schizophrenia with severe defect. Within this continuum particular forms of illness are genetically related to those nearby. The inter-relatedness of the two ends of the continuum, however, is limited.

The hypothesis of a continuum of psychosis is a development of the concept of the 'unitary psychosis' espoused in the last century by Guislain, Neumann, and Griesinger and more recently by others (Llopis, 1954; Menninger *et al*, 1958; Karlsson, 1974; Renner, 1982; Flor-Henry, 1983). The refinement is that the psychoses are represented on a continuum (Fig. 4) from pure affective illness to deteriorating schizophrenia.⁷

FIG. 4 The continuum concept. Brackets indicate the range over which mood-incongruent psychotic phenomena and nuclear symptoms may occur

That movement along this continuum occurs is documented by Ødegaard's study and the studies on schizoaffective disorder; that such movements take place in the course of reproduction is suggested by the systematic trend in the intergenerational studies. For the children of parents with one type of psychosis the risk of an illness of greater severity is increased. These phenomena cast some light on the nature of the underlying genetic mechanisms. They intimate that in the psychoses we observe the manifestations of quantum changes in a variable gene. One possibility is that at some critical stage of the reproductive process (e.g. meiosis, fertilisation) tandem repeats of a mobile genetic element (or of some component of that element) are generated.

The nature of the psychotic continuum

The persistence of the psychoses in spite of a fertility disadvantage, well documented in the case of

schizophrenia but possibly also associated with manic-depressive psychosis (Stevens, 1969), raises the question of whether the gene confers advantages on relatives of patients with psychotic illness. In Iceland, Karlsson (1984) noted that such relatives were over-represented, as recorded in the Icelandic *Who's Who*, in public life and the professions. Karlsson (1978) also drew attention to the frequency of a history of mental illness in compendia of those distinguished in literature, mathematics and philosophy. Others (Andreasen & Powers, 1975; Jamison, 1986) have documented the prevalence of significant affective disturbance in writers and poets. The nature of the relationship between the two typical psychoses and achievement is illuminated by Noreik & Ødegaard's (1966) study of Norwegians with a background of higher education. Among high school graduates they found admissions increased with respect to general population expectation for a diagnosis of manic-depressive psychosis in both sexes and for schizophrenia in females. In studying admission rates in relation to occupation, they found that the group comprising the liberal professions, teaching and higher officials had first admission rates for manic-depressive psychosis twice those of the general population (151, compared with 73), but admission rates for schizophrenia were reduced (305, compared with 357 for the general population).

Such associations suggest that the gene has beneficial as well as adverse consequences, and that the balance between them is seen only when the psychoses are considered together. However, it remains to be demonstrated that these effects are related to gene survival. There appear to be two possibilities—that the gene or a component element promotes fertility in (as yet unidentified) relatives of psychotic individuals, or that the element is able to replicate between haploid genomes, as suggested for mobile genetic elements by Hickey (1982), and thus to persist against a fertility disadvantage.

A clue to the nature and functional significance of the variable underlying psychosis is Flor-Henry's (1969) observation that the psychoses associated with temporal lobe epilepsy are commonly schizophrenic when the lesion is on the left side and affective when it is on the right side of the brain. Recent (and some earlier) studies of brain structure support the view that schizophrenia itself is a disease with a degree of selectivity for the left hemisphere (Crow, 1986). Such observations raise the possibility that the genetic determinants of brain lateralisation and psychosis are related.

Asymmetries in the human brain are now well established (Galaburda *et al*, 1978): structures in the superior temporal lobe, including the auditory

association cortex, are better developed on the left than on the right side of the brain (at least in right-handed individuals). These asymmetries are a relatively recent evolutionary development being shared by man with the gorilla (Groves & Humphrey, 1973) the orang utan (Le May & Geschwind, 1975) and the chimpanzee, but not the rhesus monkey (Yeni-Komshian & Benson, 1976). Presumably they are related to the cerebral mechanisms of communication and speech. In man the asymmetries are associated with cerebral dominance and handedness, a genetically determined attribute whose persistence as a polymorphism is as yet unexplained.

Since differential brain growth occurs, one must suppose that the genes involved code for one or more growth factors. These genes, e.g. the 'cerebral dominance gene' or 'right shift factor' (Annett, 1978, 1985), could be the location of the genetic changes underlying psychotic illness. One possibility is that a viral gene (e.g. a retrovirus or other type of mobile genetic element or 'transposon') is integrated at this site (Crow, 1984). If the presence of such a gene were associated with increased growth but the gene was sometimes expressed as viral particles this could explain the postulated benefits as well as the disruptive cerebral effects, and possibly the episodic nature of the illness.

Conclusions

It is concluded that the affective psychoses and schizophrenia are related to each other on a continuum, and that this continuum has a genetic basis. This concept is founded in the failure of Kendell & Goulley's attempts to separate the conditions by symptomatology and in the similarities in season of birth and season of onset effects for the two prototype disorders. It is sustained by observations that schizoaffective psychoses (states defined as intermediate between the major psychoses) do not breed true and cannot be excluded from the relatives of patients with affective disorder or schizophrenia when these are defined by stringent criteria. Therefore, by an inductive (in a mathematical sense) argument as well as from the evidence of studies of symptomatology and outcome, there is a case for a continuum of psychosis which increases in severity from unipolar through bipolar affective disorder to schizoaffective disorders and schizophrenia with increasing degrees of defect. The existence of such a continuum and the excess of individuals with schizophrenia among the descendants of patients with affective disorder provide clues to the nature of the genetic mechanisms. The genes responsible appear to

be subject to quantum changes. Perhaps these genes survive because they are closely related to growth factors responsible for the development of cerebral asymmetry and the mechanisms of dominance. Such relatively late evolutionary developments may be associated with a high degree of genetic variation.

Notes

1. According to G. E. Berrios (in preparation), the concept of functional psychosis is unlikely to have originated with Kraepelin, although it was adopted by him. It may have been introduced by E. Mendel.
2. Cammer (1970) also commented on the incidence of schizophrenia in the children of manic-depressive parents. In a personal case record study he judged that 148 (26.6%) of 533 children of 273 manic-depressive parents were "schizophrenics", but the diagnostic criteria adopted are broad and the age structure and hospitalisation histories of this series were not given.
3. It is of interest that in Gershon *et al.*'s (1982) investigation there was an excess ($P < 0.001$) of schizophrenia among the relatives of patients with schizoaffective illnesses in comparison with those having other types of affective illness. Also of note with respect to inter-generational effects is the finding that the risk of schizoaffective illness in the siblings of the generation succeeding the proband is increased (at 3.9% age-corrected lifetime risk) in comparison with siblings of the proband (0.8%) and siblings of members of the generation preceding the proband (0%).
4. It is also of interest that an earlier study (Tsuang *et al.*, 1980) of the Iowa series, which did not allow schizoaffective diagnoses, supported the distinction between schizophrenia and affective disorder "although the distinction between schizophrenia and mania was not clear-cut". Subtyping of paranoid and non-paranoid schizophrenia and of unipolar and bipolar affective disorder on the basis of familial associations was not supported. These conclusions do not appear to rule out a continuum concept.
5. A number of studies have related outcome in schizophrenia to incidence of atypical or affective psychoses in relatives. Thus Kant (1942) studied family histories of 50 deteriorated and 50 recovered schizophrenic patients and found that while overall rates of psychosis were similar in the two groups, the ratio of schizophrenia to affective disorder was 5:1 in the former and 1.5 in the latter. However, he notes that "none of the manic-depressive patients among the relatives of the recovered group actually belong to the manic-depressive nucleus... there are several whose clinical pictures remind one strongly of the corresponding atypical types in the recovered schizophrenic group". With a parallel strategy, Kendler & Hays (1983) studied patients with schizophrenia diagnosed by DSM-III criteria, and identified a group of 18 with a first-degree relative with unipolar affective disorder and 10 with a relative with bipolar affective disorder, whom they compared with a group of 98 with no affective disorder in first degree relatives. These authors commented on their own and some other authors' apparently high rates of affective disorder in relatives as "probably representative of most families of schizophrenics". Patients with a family history of affective disorder were more likely to have suffered from affective symptoms on follow-up. Kendler & Hays concluded that "even when DSM-III criteria are met, hesitation is indicated in diagnosing schizophrenia in patients with a first degree relative with bipolar illness". Similarly, Pope & Lupinski (1978) review 15 studies of "good prognosis", "remitting", and "recovered" schizophrenia and "atypical", "schizophreniform" and "schizoaffective" psychoses and draw attention to the high frequencies of affective illness in the relatives. They warn that "over-reliance on (clinical) symptoms alone results in over-diagnosis of schizophrenia and under-diagnosis

of affective disorder, particularly mania. This compromises both clinical treatment and research".

Underlying the views of Kendler & Hays and Pope & Lipinski is the conviction that the binary concept is correct, but that the location of the borderline has strayed from its position of Kraepelinian rectitude, if this borderline were replaced, symptoms and outcome would separate in the prescribed bimodal manner. The work of Kendell & Gourlay (1970) and Kendell and Brockington (1980) gives no support to this notion. Moreover, in the recent literature the border has moved far in one direction and then far in the other without finding a satisfactory resting place. It is clear from the work of Kendler & Hays (1983) and Kendler *et al.* (1985) that the DSM-III criteria do not locate it. It has to be considered that no such natural resting place exists.

6 A recent independent challenge to the Kraepelinian viewpoint is the suggestion that the clinical picture in the individual patient is less constant than is often thought. Thus Sheldrick (1975) and Sheldrick *et al.* (1977) draw attention to a group of patients who present with apparently typical schizophrenic illnesses but later suffer from episodes of illness which are affective in form. Conversely, Kendler & Tsuang (1982) report a pair of monozygotic twins, each of whom progressed from typical affective illness to 'process' schizophrenia. They suggest that the progression is genetically determined. Most unexpected, from a Kraepelinian and a genetic viewpoint, is the

report of McGuffin *et al.* (1982) of identical triplets discordant for psychosis according to binary typology. Each of these findings appears to be exceptional (although the precise frequency of such exceptions is of considerable interest), as can be seen from the findings of the major studies (e.g. Tsuang *et al.*, 1980; Gershon *et al.*, 1982; Kendler *et al.*, 1985), which document the relative stability of clinical picture within families.

7. Ødegaard's (1963, 1972) conception of a "multifactorial" genetic background was based on observations of overlap in family studies in series of consecutive admissions. The notion was particularly well developed in the 1972 paper, in which the range of diagnosis in the proband was extended (Fig. 3). A 'spectrum' concept of the psychoses was also formulated by Beck (1972), without reference to genetic studies. Beck considered that two variables were involved—a schizophrenic variable linked to a poor prognosis, and an affective variable linked to a good prognosis.

The Attachment Dynamic in Adult Life

D. H. HEARD and B. LAKE

A case is presented for regarding the Attachment Dynamic as a theoretical model for hypotheses on the aetiology and management of neuroses and personality disorders. It is proposed that man has a number of natural propensities, including: (1) attaining 'companionable interactions' with peers, in which competence is affirmed, self-esteem enhanced, and a state of well-being ('assuagement') is promoted. (2) when hindered in the pursuit of interests and companionable interaction, an urge to seek support through proximity to, and often 'supportive interaction' with support-givers. (3) severe psychological distress ('disassuagement') when support-givers cannot be induced to act effectively, with a propensity to devise defensive strategies, supplemented by psychological defence mechanisms; when maladaptive, these strategies are the source of neurotic symptoms and antisocial traits. Through these propensities, movement between companionable interaction and effective support sustains the urge to develop skills and explore interests creatively. However, this movement is hindered by the experience of repeated disassuagement and the need to maintain maladaptive defensive strategies.

Clinicians working with adults continue to look for more reliable and testable theoretical models that can be used as a basis for examining and treating patients suffering from various forms of psychopathology, notably neuroses and personality disorders. Much interest has been aroused by Bowlby's Attachment theory (Parkes & Stevenson-Hinde, 1982) but clinicians have had difficulty in using it as a developing conceptual framework (Bowlby, 1980) or as an open-ended model (Ainsworth *et al.*, 1978). There are three major impediments to the fuller use of Attachment concepts in clinical work. Firstly, as it stands, the theory is not sufficiently comprehensive to be used as a basis for the assessment and management of adult patients. Secondly, the predominant emphasis on objective observation in the way the theory is framed, while constituting an attraction for behavioural scientists, under-emphasises the significance of a patient's experience, which is an essential currency for clinicians. The third impediment is the absence of a sufficiently formulated definitive framework that can act as a bridge between attachment phenomena in children, on which the theory was developed, and those phenomena in adults.

The theoretical model which we outline here, is a minimum first step to deal with these limitations. It is a development of the concept of the Attachment Dynamic (Heard, 1978, 1982), reformulated to generate hypotheses regarding the aetiology, management, and treatment of neuroses and personality disorder. Clinical findings can then be used to

correct the theoretical statement, and to determine its explanatory power.

Basic Concepts

The concept of the Attachment Dynamic (Heard, 1978, 1982) emerged from integration of the theoretical innovations of Bowlby (1973, 1980, 1982) with the experimental findings of Ainsworth (1969, 1977) and the insights of Winnicott (1971, 1972). The first version outlined an interpersonal dynamic which sets out some of the situations in which three kinds of behaviour relate to one another, namely (1) care-giving, (2) care-seeking (attachment behaviour) and (3) exploratory behaviour or play, as conceptualised by Winnicott (1971).

The transition to this second version came about after the concepts on which the first was based were integrated with concepts of: (1) peer interactions; (2) competence, mastery, and self-esteem (Hendrick, 1947; White, 1959; Frank, 1979; Phillips, 1967); (3) demoralisation (Frank, 1979); (4) the closed sado-masochistic system (Fairbairn, 1952; Rubens, 1984), and (5) qualities of interactions (Hinde, 1979).

Two experiences led to the transition. The first entailed clinical observations on adult clients who showed distress over the absence of like-minded companions of similar experience and stamina with whom to engage in mutually interesting and enjoyable activities. This evoked the concept of 'companionable interaction' as an essential component of exploratory behaviour. The second experience arose during the translation into operational terms of the concept of ego strength (Lake, 1985) by rating observable abilities in terms of personal and social competence. This brought together ideas from a number of different schools

of thought, and led us to focus on the commonplace concepts: (1) that an individual's monitoring of his/her own effectiveness is essential for the attainment and maintenance of selected goals, (2) that such monitoring is markedly influenced by the views expressed by those he holds as significant, and (3) that the recognition of potential and actual competence by others, as well as by oneself, is commonly associated with a sense of increased well-being. Lack of such recognition is associated with loss of autonomy and with a sense of being devalued.

This new emphasis prompted us to distinguish (1) two interpersonal, continuing goals for the dynamic of companionable interaction, and of supportive interaction; and (2) the conditions which in everyday life lead individuals to seek one goal rather than the other. It is important to distinguish the set goals of the dynamic from its function. The function enables man to survive by developing exploratory propensities, executive skills, and autonomy, within a limited but expanding network of trusted relationships. In so doing, man maintains his "environment of evolutionary adaptiveness" (Bowlby, 1982), which enables him to evolve features distinguishing him as a species. An essential feature of man's environment of adaptiveness is the continuing presence, in the life of each individual, of a hierarchy of preferred relationships through which a state of 'assuagement' can be maintained.

Attachment Dynamic in Adults

Intrapsychic events will be described from the point of view of an individual's experience; as the dynamic describes movement between interpersonal aims, we have to break into a "story" (Medawar, 1967), which is circular.

Companionable Interaction and the state of 'assuagement'

The concept of companionable interaction is supported by research on the social behaviour of children (Mueller, 1979), Harlow & Harlow's (1965) concept of peer-peer affectional systems, and Hartup's (1980) observations on peer interaction and the growth of social competence. It has an affinity with Murray's (1938; 1959, Murray & Kluckhohn, 1953) concept of affiliative relationships, Sullivan's (1953) conceptualisation of the relationship between 'chums', and corresponds closely to Weiss's (1982) concept of affiliation.

The exploratory nature of companionable interaction

We postulate that individuals have a natural propensity to have 'companionable interactions' in specifiable circumstances with peers, i.e. people of broadly equivalent intelligence, stamina, capacity to handle fear and panic, and competence in the pursuit of interests. Companions are peers who have similar commitments to sharing one or more interests. Companionable interactions may take place in twosomes, threesomes, or in small or larger groups. It has the function of providing both shared awareness and understanding of an interest, and the recognition of competence; such interactions are therefore episodes in an exploratory

endeavour. 'Interest' is used in the most general sense for work and leisure activities, e.g. dancing, football, teaching, cooking, engineering, and literature; some are pursued alone, with episodes of companionable interaction, while others are more social, and the interest is pursued in small groups.

Factors evoking companionable interaction

Factors which evoke the seeking of companionable interactions include: (1) reaching new levels of understanding in regard to an interest, or of achievement in an associated skill; (2) observing other individual(s) doing likewise, (3) recognition that a companion requires support in the area of the interest, or requiring such support oneself.

Emotive messages and the goal of companionable interaction

The goal of companionable interaction is reached during the sharing of new information about an interest and the skills associated with it; this comes about through the exchange of 'emotive messages', which relate to the command aspect of a communication (Bateson, 1951). In these each participant conveys, in non-verbal as well as in verbal language, the feelings, thoughts, and wishes each has about the behaviour of the other(s). They are the means by which each participant in the interaction conveys whether or not he is anticipating, or experiencing the goal of the interaction. We describe here the emotive messages associated with reaching or failing to reach the goals of the two interactions of the dynamic. We do not discuss details of facial expressions, gestures, tones of voice, and syntax that may be used in conjunction with verbal information to communicate emotive messages, but paraphrase the spirit of the messages.

The goal of companionable interaction is reached whenever an individual construes from the emotive messages sent by companions, that they are taking interest in and showing appreciation of his contribution and the way he has made it; and at the same time, realises that the interest he is taking in the contribution of his companions is also appreciated.

'Assuagement' as a consequence of effective companionable interaction

As a consequence of experiencing the goal of the interaction, a state of mind is reached which, for want of a better term, we call 'assuagement'. In this state, there is: (1) an affective experience of mental and physical well-being, a feeling of satisfaction and enjoyment in what one is doing; (2) a sense of confidence and self-esteem in the ability to achieve short or longer-term aims which are consistent with stages of life, abilities, and interests; and (3) awareness that one's personal supportive environment is secure and that opportunities for companionable and supportive interactions are available.

In the state of assuagement, an individual is also able to: (1) consider the consequences of his actions, (2) see issues from another's point of view; (3) reappraise past experiences; and (4) integrate new approaches with known

routines to carry out short-and longer-term plans. There is also the disposition and readiness to develop ventures and pursue interests creatively, in ways that expand meaning and widen relationships with others. This purposive dimension embodies the motivation to engage in companionable interaction and so to maintain a state of assuagement. The state can consequently be considered as experience of basic trust, autonomy, and initiative (Erickson, 1965). In the contrasting state of 'disassuagement', all these abilities tend to be over-ridden.

Support and the maintenance of creative exploration

Circumstances which evoke movement towards psychological support

Support-seeking is evoked when an individual finds himself hindered in pursuing an interest and engaging in companionable interaction. This may occur through the recognition that competence and effectiveness are, or are about to be diminished (for physical or psychological reasons), or that companions are not available. Once pursuit of an interest has been threatened, psychological support is required before an individual is able to become sufficiently self-reliant to deal with the interfering circumstances. This support restores the individual's confidence in his ability to: (1) review his goals concerning a particular interest, and his relationship with companions; and (2) make and carry through plans likely to be effective; in so doing, loss of confidence is reduced, hope of acting competently and autonomously increased, and self-worth and self-esteem raised. A state of assuagement may be anticipated at this stage but support, however effective, does not in itself bring about assuagement until companionable interaction over an interest is attained.

Psychological support for adults and the use of internal representational models of experience in relationships (IMERs)

Psychological support for adults comes from two interdependent systems. An internal system interconnects with an external one which is used whenever the support provided by the internal proves insufficient. The internal system comes into being during infancy, and continues to evolve throughout life; it is derived from the experience of the interactions an infant has with principal care-givers (attachment/care-giving interactions described by Bowlby, 1982). These interactions with people in the external environment are continuously encoded into internal representational models which the individual constructs of himself and his environment. This concept of representational models has been extensively explored (Bartlett, 1932; Piaget & Inhelder, 1948; Fairbairn, 1952; Craik, 1943; Cantlil, 1950; Miller *et al.*, 1960; Young, 1964; Bowlby, 1982). We postulate that some representational models, viz. of experiences in both companionable and supportive relationships (IMERs) form the basis of an individual's internal supportive system. IMERs store information (see Appendix) in ways that enable the lessons continuously learnt from interactions to be integrated with other related experiences, so

that it can be used to: (1) construct and correct attributions about causes for success or failure in such interactions; and (2) predict how competence can be increased, and companionable and supportive relationships be found and maintained. Each relationship an individual has with others is recorded in different IMERs as a sequence of episodes, during which different kinds of interaction between that individual and another take place. Any information about the other(s) already encoded on other IMERs is added to the record, so that personal histories of particular relationships are reconstructed over time. For example, a man after marriage adds an IMER of himself relating to his wife, later an IMER of himself relating to his child, and then a third IMER of himself relating in a threesome with his wife and child. These histories include beliefs about what can be expected to take place within each relationship.

People who feature in a personal history of a relationship appear in various roles, covering every combination of companion, support-giver, or support-seeker. Thus, someone may feature in a history of a relationship as a reliable support-giver, seeking minimal support but only marginally acting as a companion; another may appear in a more reciprocal relationship, weighted towards seeking and giving support or perhaps towards companionship. The combination of roles tends to change as each partner in the relationship develops greater psychological maturity and deals with the vicissitudes of fate. When the search for support is evoked, an individual automatically uses his IMERs to provide memories of analogous situations in which he has experienced effective support, and then adds to his knowledge of the availability of effective support-givers. If these internal resources are insufficient, external support is sought.

The external supportive system: use of the personal supportive environment, attachment network and supportive interaction

The external supportive system in adults has three components. The 'personal supportive environment' describes the ambience in which an individual feels secure: this has affinities with Lewin's (1952) life space, and covers the concept of transitional and/or attachment phenomena (Winnicott, 1972; Boniface & Graham, 1979). It includes activities, recreations, personal routines, pace of life, disposition of belongings, kind of terrain and house found to be congenial; the degree of light, colour, warmth and physical comfort one enjoys; and the spatial and psychological distance from and closeness to, companions, support-givers and support-seekers found comfortable. This environment is constructed through the integration of information derived from memories of: (1) contexts in which an individual has experienced harmonious forms of companionable and supportive interaction; (2) natural phenomena and works of man which evoke a sense of wonder and often awe; and (3) religious experience.

Such memories are distilled from information in the IMERs, and act as a vision of a secure environment which an individual sets about creating in tangible form by means of the style in which he lives his everyday life. Whenever an individual is unable to maintain enough of his personal

supportive environment to supply the reminders necessary to supplement the internal supportive environment, he checks over the availability of preferred relationships of his 'attachment network'. Finally, if availability alone is not sufficient, supportive interaction – the third component of the external system – is sought.

'Preferred relationships' refers to relationships in which individuals regularly expect to find opportunities for companionable and/or supportive interactions which are experienced as more rather than less effective. People who are so classed constitute an individual's attachment network, and the degree to which they are preferred establishes a hierarchical order of preference. The concept of preferred relationships in the attachment network circumvents difficulties in describing attachment relationships and affectional bonds in adults (Parkes & Stevenson-Hinde, 1982; Ainsworth, 1982; Weiss, 1982; Cohen, 1974; Svejda *et al.*, 1982). Preferred relationships are experienced in twosomes, threesomes, or small groups; the people concerned will tend to be members of an individual's family and close friends, though we are inclined to include well-loved pets in the network of some people. An individual's attachment network varies in size and composition throughout life, as opportunities for interaction come and go, as commitment to different interests wax and wane, and as locality changes. In response to such changes, those people who remain in the network over a considerable time may move up and down the hierarchical scale. The place a person occupies on this scale at any one time appears to be reviewed regularly on the basis of how: (1) available and enjoyable that person is as a companion; (2) available and effective as a support-giver; (3) congenial as a support-seeker in situations in which support may be sought; and (4) the degree to which defensive strategies and the personal supportive environments of the individuals concerned are compatible.

Effective supportive interaction, its participants, and associated emotive messages

Supportive interaction takes place between one or more individuals who seek support and one or more willing to give it. Support-givers who are able to fulfill the role have greater experience, stamina, and judgment in the areas in which support is sought, as well as a greater capacity to handle the anxiety and fear that may be generated by the circumstances in which support has to be given. The aim of support-givers is to provide the support-seeker with the appropriate mixture of comfort, protection, and relevant educative information that enables the seeker to choose the lines of action that best suits his needs and aims. The aim of the support-seeker is to elicit the mixture that enables him to reappraise his goals and his attitudes about himself, and to remake plans, so that he can return with some confidence to old or new interests and companionable interaction. This mixture is found and given during one or more episodes of interaction, over the period required for the support-seeker to make his reappraisal. The giver finds the effective mixture by being attentive to the seeker's emotive messages and, guided by his empathic understanding of the messages, modifies his behaviour so that the seeker approaches the goal of the interaction. In supportive interaction, the

seeker's emotive messages signal to the giver whether the mixture on offer is good enough, whilst the giver's emotive messages signal his willingness or refusal to adapt the mixture until the goal is reached.

Emotive messages and psychological proximity

To discuss issues of agreement or conflict over the messages expressed by the giver or seeker, we have extended Bowlby's concept of the need for physical proximity to preferred persons in defined circumstances, by introducing the notion of the need for comfortable psychological closeness and distance from such persons; and we contrast it with uncomfortable or distressing psychological distance or closeness (impingement). Comfortable psychological closeness is experienced by individuals whenever they consider their interactional goals are being approached or attained. Uncomfortable psychological closeness or distance is experienced whenever the behaviour of the other(s) is antithetical to the goals of the particular interaction.

Emotive messages exchanged between giver and seeker, during a period in which comfortable psychological closeness is experienced by both, show that each is prepared to relate to, be interested in, and value (although maybe not agree with) the feelings, ideas, and actions expressed by the other. Furthermore, each shows he is prepared to relate to the other, whatever aspects of personal supportive environment or form of defence the other is using. Finally, the support-giver shows pleasure and enjoyment in the seeker's achievements. In effective support, the giver notices the messages from the seeker which indicate uncomfortable closeness or distance, and adapts the mixture of support he offers until comfortable psychological proximity is re-established. Furthermore, the giver monitors his own requirements for support, and if necessary interrupts giving in order to gain support for himself elsewhere.

Consequences of experiencing effective support

Whenever a support-giver recognises that the seeker is able to carry out effective plans that enable the interest(s) about which support has been sought to be resumed or changed, the giver feels free to diminish proximity and to attend to other affairs. For the support-seeker, the end-point of the interaction is the realisation that he can make plans that are likely to enable him to find companionable interaction – through resuming the pursuit of a particular interest or engaging in another – and also maintain a comfortable physical and psychological distance from the support-giver. Provided the most effective members of an individual's attachment network remain available and the individual can maintain the most essential features of his/her personal environment, each experience of effective support increases expectations of finding such support in the future, by increasing the adequacy of his internal supportive system.

The integration of effective companionable and supportive interaction

Companionable and supportive interactions are seen in

combination throughout life. Integration can be seen from the time of the first social smile, when exploration of interests and companionable interaction needs to be enjoyed within a framework provided by support-givers, until a child is old enough to pursue mutual interests with peers. The roles taken in companionable and supportive interaction are influenced by epigenetic factors; they show different forms, commensurate with concurrent levels of psychological and physical development and interactional experience encoded in the IMERs. The most significant contribution from the IMERs which influences the effectiveness of the internal supportive system is the balance between experiences of effective and ineffective support-giving from the support-givers and companions. Experience of both effective and ineffective support is common to all, an individual draws on one or other of these types of experience in different contexts, using them as models of giving support both to himself and to others. Examples of the combination and integration of companionable and supportive interaction can be seen in the ordinary pursuit of interests with companions, in friendships, and sexual relationships based on companionship.

Support as part of companionable interaction

It is commonly observed that companions give each other support (effective or ineffective) whilst pursuing or attempting to pursue an interest, in either work or recreational settings. Interests are pursued most competently in adult life when companions show each other a sufficient degree of effective support in the development and practice of the requisite skills. However, it is not possible to give attention to the exploratory pursuit of an interest, and simultaneously give effective support in an area outside that interest, although the two activities may alternate with each other, as can be observed in friendships.

Friendship, shared interests and reciprocal support

We regard friendship primarily as a companionable relationship, within which interests are enjoyed and support given and received, not only in the pursuit of shared interests but embracing other aspects of life. The more issues over which companionship and reciprocal support can be expected and the more compatible the defensive strategies and personal supportive environments, the closer and deeper the friendship and the more its loss will be mourned. The weighting given to interest-sharing and reciprocal support as an aspect of friendship means that relationships with parental figures will tend to move down the hierarchy of the attachment network, as an adult grows older.

Sexual relationships as a form of intimate friendship

Another example of the integration of companionable and supportive interaction is found when peers express and explore sexual interests. We distinguish two categories of sexual interest: (1) sexually intimate friendships, characterised by shared interests and reciprocal support, to which shared sexual attraction is added, experienced as an

intensely enjoyable sense of physical and psychological closeness. The more sexually intimate the friendship, the greater its claims to the highest place in the hierarchy in the attachment network (2) defensive sexual relationships, characterised by an absence of friendship

Ineffective support, defense and disassuagement

We have considered how the Attachment Dynamic maintains and develops an individual's creative capacity, but should supportive interaction fail to take place (support figures not being available when needed, or available but regularly acting in ways that are antithetical to the goals of supportive interaction) the sense of inadequacy that evoked support-seeking in the first place is exacerbated, and a state of distress – 'disassuagement' – is experienced. Regular and/or intense experiences of such disassuaging interaction induce individuals to devise defensive strategies, in order to reduce intolerable distress and to restore self-esteem and the potential for competence; as a result, interests associated with ineffective support are either pursued with anxiety or abandoned. In these contexts, the supportive system has been put under stress, and the individual either evades companionable or supportive interactions, or else engages in them in maladaptive ways that are tormenting or damaging to himself and/or others.

A view of defensive processes in the attachment dynamic

Psychological processes of defence are a complex and contentious field of study; this discussion will be limited to a view which considers that defensive processes are designed to handle the pain of disassuagement and the fear of loss of autonomy. This derives from psychotherapeutic encounters with clients and from consultations over the management and treatment of patients suffering from neurosis. We find it useful to consider defensive processes as: (1) behavioural strategies which are, for the most part learnt; (2) processes which involve the concept of automatic selective exclusion of information (Bowlby, 1980), and the general paradigm that memory is structured in ways that allow us to learn from experience, using the phenomena of reminding in the process (Schank, 1982).

Disassuaging experiences stored in individual IMERs are partially or wholly segregated from conscious awareness, through automatic exclusion of information. A similar view was expressed, in different terms, by Fairbairn (1952), Guntrip (1961, 1968), and Kernberg (1976). These stores are kept under surveillance, in such a way that any current circumstances that seem similar to previous disassuaging events act as reminders of them; such reminders appear to be glimpses into segregated events, and evoke a wide range of conscious experiences. The glimpses range from re-experience of intensely distressing affects to an apparently inexplicable recall of some incident – with or without any particular affect – which, on later reflection in a supportive setting, is connected with a distressing event. They also elicit defensive patterns of behaviour, seen e.g. in transference and counter-transference phenomena. Using whatever degree of sophistication their cognitive development can command, individuals supplement automatic responses by

devising strategies to minimise each particular type of regularly repeated ineffective support. Once an effective strategy is learnt with particular support figures, it tends to become habitual with those figures, and generalises to analogous situations, so becoming a character trait.

Defensive strategies, although adaptive in the context in which they are devised, may be grossly maladaptive when used in contexts which only seem similar to the original. These strategies are recognised by the presence of the compulsive pursuit of closeness to or distance from certain people, settings, and activities; they include both compulsive sexual activities, many of which may be deviant, or a total inhibition of sexual activity. Common examples include (1) inducing ineffective support-givers in the network to interact in ways that are less disassuaging, through compulsively compliant or rebellious behaviour (2) excluding from supportive interactions persons predicted to be more successful in claiming the attention of a support-giver—a common aspect of sibling and other forms of rivalry (3) staying in contact with ambivalent support-givers by creating the illusion that they are effective, through the selective exclusion of contrary information. Common examples of defensive strategies associated with an individual giving up the pursuit of proximity to ineffective support-givers, include imagining effective interactions with idealised support-givers, or the ruthless exaction of retribution from punitive and rejecting figures

tend to reverse roles and seek support rather than give it, or mask their own disassuagement by defensive strategies.

Description of disassuagement

States of disassuagement are frequently masked by defensive strategies, and are revealed in adults when defences have been breached or when undefended losses are sustained, as in natural mourning. The clinical picture fits Frank's (1979) description of demoralisation and Engel's (1968) giving up/given up complex, in their somewhat less severe forms. Briefly, an individual suffers loss of a sense of confidence and competence in his ability to manage not only external circumstances, but his own feelings and thoughts, and tends to lose faith in what previously gave him a sense of security and significance. These losses reactivate memories of earlier losses and failures, and increase feelings of helplessness and hopelessness. A sense of low self-esteem is induced, frequently associated with guilt and shame, the individual loses sight of his long-term goals, and is preoccupied with avoiding further failure and loss of autonomy. Resentment is commonly felt because those from whom help is expected seem unable or unwilling to give it. In states of disassuagement, depending on the effectiveness of defences, the dominant moods are those of anxiety, irritability, and depression, ranging from mild to severe.

The emotive messages of ineffective support

Psychological distancing which is uncomfortable and distressing arises; firstly, when a companion or support-giver fails to recognise or acknowledge a request for supportive or companionable interaction, or having recognised it, devalues or rejects it; and secondly, when someone assumed to be either a support-giver or -seeker refuses to accept the expected role. In contrast, uncomfortable and distressing closeness arises when individuals, as seekers, are pressurised to accept unsolicited support and/or support they construe to be inappropriate and inadequate, or as support-givers, are subjected to intense demands which they cannot satisfy. In each instance, giver and seeker put each other under painful pressure to accept the meaning and point of view of the other. Giving in to such pressure is frequently experienced as submission, with loss of autonomy which increases the experience of disassuagement.

When psychological distancing or closeness becomes increasingly uncomfortable, messages from each participant express frustration, tension, and increasing fears of being hurt by or of hurting the other. If unacknowledged, such messages, tend to be repeated with escalating degrees of emotional intensity, and epitomise a struggle to regain comfortable psychological proximity or relief. Anger in such situations is frequently an expression of the intensity with which an individual endeavours to force the other to comply with his wishes and beliefs. During such struggles, each of the participants fails to be empathic, and the capacity to negotiate differences is severely limited. Adult support-givers are usually ineffective only when they find themselves having to give support when they themselves need supportive interaction. In such circumstances, they

Disassuagement and the three forms of the Dynamic

We distinguish three forms in which the Dynamic is expressed and disassuagement experienced—one adaptive and two maladaptive. Each is associated with different levels of an individual's exploratory capacity, defences, and the effectiveness of his internal and external supportive system. These factors lead to the development of three different approaches to the pursuit of interests—companionable interaction, support-giving, and support-seeking, and hence to three different forms of the Dynamic.

Disassuagement and the adaptive form of the Dynamic. This form has already been described. It is shown when individuals have enjoyed and anticipate sufficiently effective support and companionable interaction over a range of interests, so that few interests are obstructed by defensive strategies. Disassuagement is suffered by these individuals following the threat or actual loss of highly preferred and effective support-givers, e.g. following natural catastrophe or loss of contact. The experience is seen in pangs of homesickness, or in grief, when mourning is followed by natural resolution over time.

Disassuagement and maladaptive forms of the Dynamic associated with anxious exploration. These forms of the Dynamic occur whenever individuals have been exposed over long periods of time to the experience of ambivalent and/or highly conditional support with key figures. The experience of ineffective support in relation to a few interests is probably a universal experience. When, however, affected interests are widespread and the internal system is

relatively inadequate, the individual has to rely mainly on the external supportive system. Interests are pursued with anxiety, and only in so far as defences will allow, so that the capacity for effective support-giving and companionable interaction is limited.

Disassuagement and maladaptive forms of the Dynamic associated with pseudo-assuagement In these forms of the Dynamic, support has been less effective, more inappropriate, and less predictable than in those associated with anxious exploration. The support-seeker has few expectations of being able to gain realistic appreciation and/or recognition of his abilities and work, over the range of interests associated with disassuagement. In these areas, the goals of companionable and supportive interaction have been replaced by a secondary defensive goal – pseudo-assuagement – which is egocentric and markedly hedonistic. We adopted this term because individuals give up the search for supportive and companionable interaction associated with a creative pursuit of interests in work or recreation to become compulsively attached to various forms of excitement and relief.

When disassuagement is associated with almost everything an individual does, it is experienced as a severe form of demoralisation and associated with a pervading sense of futility. Defensive responses which have to be continuously maintained include: Firstly, types of maladaptive self-support which enhance various forms of self-comfort, geared to providing immediate relief from tension, e.g. common forms of addiction associated with denial and rationalisation; and secondly, forms of defensive companionship in which various modes of achieving excitement and/or status are idealised and pursued as ends in themselves. However, the search for effective support is seldom completely abandoned, and should appropriate skilled support be found, the primary goal of the Dynamic may be reinstated.

Individual styles within the attachment Dynamic

The forms in which the dynamic may be expressed in different contexts contribute to an individual's unique personal style, e.g. the way the Dynamic is expressed over a day may change from an adaptive form to forms associated with anxious exploration or pseudo-assuagement, as an individual moves from life at home to work, or to leisure activities. Similarly, individual styles in maintaining the goals of the Dynamic are likely to change over a lifetime, as different developmental stages are approached and life events affect the opportunity to maintain an effective attachment network and personal supportive environment. An observer of any one area or stage of an individual's life will therefore see only that one aspect of the total picture. However, it is possible, for clinicians to work out the style in which the Dynamic is currently, or has previously been expressed by examining the present nature and history of: (1) states of mind associated with companionable interaction, and both roles of supportive interaction; (2) the size, availability, and effectiveness of the attachment network; (3) emotive messages concerning psychological proximity regularly used

during companionable interaction, and in both roles of supportive interaction; (4) the level of commitment to, and effectiveness in the range of interests pursued in the various contexts of everyday life; and (5) the kind of personal supportive environment maintained and the degree of preoccupation in maintaining it.

Discussion

The outline we have presented represents a loom on which may be woven the rich, elusive and at times repellent tapestry of human relationships. Our concern has been to set up a sufficiently comprehensive warp to investigate the possibilities and limitations of human potentialities.

This model leads to the conclusion that men and women cannot be co-operative and look after themselves and others unless they can enjoy practising skills that reveal creative talents with their peers. But the model shows that this can best be achieved when individuals live in the secure knowledge that they have relationships with people who recognise their potential for creativity, and who can provide information, protection, and comfort that enables them to restore the experience of competence, whenever their skills are no longer effective. Whilst recognising the intensely destructive nature of certain defences against disassuagement, the model suggests that much hostile aggressive behaviour is a strategy to handle fear concerning survival, arising from failure to find effective support.

Experience of sustained disassuagement is associated with psychopathology, which can range from mild to severe forms of neurosis, personality disorder, and borderline state. In our view these disorders are manifestations of an interplay between constitutional factors, the history of past interactions in preferred relationships encoded in the IMERs at all stages of life, and 'here and now' experiences in social relationships. Therefore treatment should take into account both the history encoded in the IMERs, and the quality of the interactions with those who provide formal or informal treatment. Some of the features of the therapeutic relationship required are discussed by Frank (1979) according to the model of the Attachment Dynamic, these are highly specific elements of effective supportive interactions, and will therefore play a part in all forms of management, counselling, adult peer self-help groups, different forms of individual and group psychotherapy-psychoanalytic and cognitive behavioural, and family therapy.

It should not be thought that all psychological distress, particularly that associated with organic disorders, depressive illness and schizophrenic disorders, is primarily a manifestation of states of

disassuagement. Loss of competence is, however, associated with any illness, physical or mental, and because it evokes a desire for support, it will exaggerate co-incidental neurotic manifestations.

We conclude with a reminder that the aim of this model is to generate hypotheses regarding the aetiology, categorisation and treatment of neuroses and personality disorder and to modify the theory in the light of the findings.

Appendix

Information in each IMER is stored in chronological order, and relates to: (1) the content of verbal exchange during interaction and the perception of the meaning of emotive messages; (2) perception (from the five senses) of the environment in which interactions take place; (3) other environmental information preceding or following the interaction that is available for association with it. We class these three categories as external information, and think that most attention is given to information relating to one's value, the roles one is expected to take, the rules one is expected to follow, and the level of performance required.

Other information comes from internal sources: (4) affective responses to environmental information regarding oneself, others involved in the interaction, the surroundings, and perceived consequences. (5) information related to defensive strategies, including handling disassuaging

relationships through phantasies of revenge, retribution, idealised forms of pleasurable interaction, and/or attaining levels of unparalleled admiration and esteem. (6) the evaluation of one's worth and performance after comparison with: (a) information already stored in the IMERs of previous interactions with appearances similar to those currently evaluated; (b) external information from other(s) before, during, and after the interaction, concerning one's worth and performance; and (c) one's personal judgment of personal performance concerning immediate and/or long-term aims.

On the basis of these evaluations, beliefs about one's worth and capacity to perform effectively are revised or confirmed, and rules concerning conduct formulated. However, there are two instances when the opportunity for revision and/or reappraisal is severely restricted: (1) instances where similar events have been followed by similar consequences over lengthy periods of time, and habituation has occurred; (2) the defensive segregation and systematic exclusion of disassuaging information.

We conceptualise the self as a form of "overall dynamic structural matrix" (Sutherland, 1979; Kernberg, 1980), constructed so that an individual can: (1) relive his experiences within a particular IMER or some part of it; (2) compare and contrast himself in different relationships and different contexts by extracting information relating to his experience from a number of IMERs. We consider that the latter facility underlies the phenomenon of the observing ego, which probably develops after infancy, but is often overridden during experiences of disassuagement.

When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P., an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal adult dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £3.73. **Product Licence Numbers:** PL0014/5941, PL0014/0209. © The Boots Company PLC, Nottingham, England. Further information available on request.

COMFORT MOOD DEPIXOL[®]

CONC. 100 mg/ml

cis(Z)-flupenthixol
decanoate

Depixol Injection and Depixol-Conc. Injection contains cis(Z)-flupenthixol decanoate, 20mg/ml and 100mg/ml respectively, in thin vegetable oil. **Indications** Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or pathology. **Dosage and Administration** By deep intramuscular injection, 1-2ml every 2-4 weeks, up to a maximum of 400mg weekly. **Children** Not recommended for children. **Side-Effects** Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose

reduction or anti-Parkinson drug treatment. **Contra-indications** Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy. **Package Quantities** Boxes of 10 x 20mg (1ml), 10 x 40mg (2ml), 10 x 100mg (1ml) ampoules; 5 x 20mg and 5 x 40mg syringes; 1 x 200mg (10ml) and 1 x 500mg (5ml) vials. **Further information** Overdosage should be treated: (a) By anti-

cholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked. **Basic NHS Cost** 10 x 20mg amps £15.53; 10 x 40mg amps £25.99; 10 x 100mg amps £59.53; 5 x 20mg syringes £8.51; 5 x 40mg syringes £13.74; 200mg (10ml) vial £14.74; 500mg (5ml) vial £28.27. (Prices correct at time of printing.)

Significance of Positive and Negative Syndromes in Chronic Schizophrenia

S. R. KAY, L. A. OPLER and A. FISZBEIN

Positive and negative syndromes were studied in relation to demographic, historical, genealogical, clinical, psychometric, extrapyramidal, and follow-up measures of 101 chronic schizophrenic patients. The criterion scales proved to be reliable, normally distributed, and strongly correlated with general psychopathology, but otherwise inversely related to one another. Multiple regression analysis identified sets of 4-6 independent variables that explained 74%-81% of the scales' variance. A positive syndrome was associated chiefly with productive features, family history of sociopathy, more previous hospital admissions, and longer in-patient stay during the 30-month follow-up period. A negative syndrome correlated with deficits in cognitive, affective, social, and motor spheres, higher incidence of major psychiatric illness but less affective disorder among relatives, lower education, and greater cognitive developmental impairment. The results underscore the importance of genetic and biodevelopmental variables for understanding schizophrenic syndromes.

The issue of heterogeneity has been at the heart of schizophrenia research since the writings of Bleuler (1911). Many efforts have been made to identify subgroups similar in phenomenology, with the hope of casting light on fundamental differences in aetiology, treatment strategy and prognosis. The early view of schizophrenia as constituting primarily a defect state along a deteriorative course (Kraepelin, 1913) has been gradually overtaken by the emphasis on productive features as pathognomonic of the disorder and even as a prerequisite for its diagnosis (Schneider, 1959; Feighner *et al*, 1972; American Psychiatric Association, 1980).

Since the beginning of this decade, Crow (1980a,b) and Andreasen (1982; Andreasen & Olsen, 1982) have proposed that these two aspects of schizophrenia may represent distinct syndromes of different aetiology. The Type 1 or 'positive' syndrome was defined by productive symptoms such as delusions, hallucinations and disorganised thinking. It was considered to issue from disturbance in dopaminergic transmission and be responsive to neuroleptic drugs, hence bearing a favourable prognosis. The Type 2 or 'negative' syndrome was characterised by deficits in cognitive, social, and affective functions, and was thought to be associated with structural abnormality in the brain, portending resistance to neuroleptics and a poor prognosis.

The fledgling research on positive and negative syndromes has provided some basis for their distinction, but the studies have generally been limited

by small samples, unstandardised rating methods, lack of long range follow-up, and no control for extrapyramidal drug side-effect (EPS) which can interfere in the assessment of motor activity, affect, and verbal productions (Rifkin *et al*, 1975; Van Putten & May, 1978). Therefore, many of the conclusions regarding aetiology and treatment response remain inferential.

Studies that relate these syndromes to differences in drug response and brain structure have yielded mixed results. Positive schizophrenic symptoms were reported to be improved by neuroleptic drugs (Johnstone *et al*, 1978a; Angrist *et al*, 1980) and worsened by anticholinergics (Johnstone *et al*, 1983), whereas the negative symptoms were essentially unaffected by either medication. In the Angrist study, however, one of the three negative parameters—emotional withdrawal—actually benefited from neuroleptics. The Johnstone group, in their assessment of 17 chronic schizophrenic patients also observed that those who had enlarged ventricles tended to have intellectual deficits and negative symptoms (Johnstone *et al*, 1976, 1978b). This finding was echoed by Andreasen *et al* (1982), although of the ten symptoms designated as positive or negative only bizarre behaviour was significantly related to ventricular size. They noted, however, greater deviation in the cognitive ratings of patients with predominantly negative symptoms, suggesting an intellectual deficiency. More rigorous experimental techniques have since found such persons slower in visual information processing (Green & Walker,

1984) but equally disordered in language production (Allen, 1983), although both these studies involved small samples (between 6 and 10).

In terms of prior functioning, patients with a mainly negative syndrome seem to have had poorer premorbid adjustment, including lesser education and work experience (Andreasen & Olsen, 1982; Andreasen *et al.*, 1982), which raises the possibility of pre-existing developmental failures. A similar finding emerged from a comparison of 39 schizophrenic patients with 33 unipolar depressives in the follow-up phase (Pogue-Geile & Harrow, 1984); negative symptoms in schizophrenia were associated with educational difficulties and poor social functioning both before and after initial admission, thus implying antecedent and sustained deficits. Since the positive-negative assessment was conducted only at follow-up, the analyses were retrospective in nature.

With expanded representation of cognitive and historical parameters, we recently carried out multi-dimensional comparisons of schizophrenic patients who showed predominantly positive syndromes with those showing predominantly negative syndromes during the acute phase of illness ($n=37$) (Lindenmayer *et al.*, 1984) as well as the chronic phase ($n=47$) (Opler *et al.*, 1984). In both studies, a positive subgroup was defined by a rating of 'moderate' or greater pathology along at least three out of seven positive dimensions and fewer than three out of seven negative dimensions (see below); a negative subgroup was defined by the reverse pattern. All other cases were disregarded.

The acute survey indicated that the negative syndrome was not secondary to the progression of the disorder, prolonged institutionalisation, severity of illness, neuroleptic dose, or EPS. Before the onset of illness, patients of this description had less schooling and poorer work adjustment. The study of chronic patients found the negative type to be older, less educated, and more often born in winter months. Despite comparable intellectual impairment and visual-motor deficit, they displayed a more primitive cognitive mode and greater psychomotor retardation. As a whole, these converging results have led us to suspect a cognitive developmental deficiency, possibly of organic basis, that underlies the schizophrenic defect state and its resistance to neuroleptic intervention.

One limitation of the foregoing studies was the typological approach, which presumes the debatable position (cf. Pogue-Geile & Harrow, 1984) that positive and negative syndromes are mutually exclusive. As a result, large proportions who failed to meet criteria for either definition (54% of the acute and 62% of the chronic group) were lost from the

analyses. The present investigation, by contrast, adopted a dimensional approach which enabled inclusion of the full sample while making no assumptions about a positive-negative bipolarity. Thus, based on the preceding assessment technique, measures were taken along three continuous scales to provide positive syndrome, negative syndrome, and composite (positive minus negative) scores. These data were studied among a larger group of 101 chronic schizophrenic in-patients in relation to a broader range of predictor variables, which encompassed demographic, historical, genealogical, clinical, psychometric, extrapyramidal, and outcome measures. By doing so we hoped to better elucidate the critical parameters underlying positive and negative schizophrenic phenomena by building into the design several methodological advantages over the previous surveys: (a) a substantial sample size; (b) the use of standardised psychometric instruments for assessing cognitive, developmental, attentional, and motor dysfunctions; (c) an expanded range of study; (d) provision of a follow-up outcome measure; (e) evaluation and control for the influence of EPS; (f) measurement of the positive and negative syndromes as both bipolar and unipolar constructs; and (g) assessment of the distribution and internal reliability of positive and negative ratings. We postulated, in line with our earlier work (Lindenmayer *et al.*, 1984; Opler *et al.*, 1984), that differences along the positive-negative dimension may be traced to premorbid developmental factors, are not mere artifacts of EPS, and may have direct implications for the future course of hospital treatment.

Method

Subjects

The medical charts of in-patients from long-term psychiatric units in a university-affiliated urban hospital were consecutively surveyed to select those having a formal DSM-III diagnosis of schizophrenia (American Psychiatric Association, 1980). Cases with questionable diagnoses, known organic disorders, or mental retardation were excluded. The final sample consisted of 101 subjects who ranged in age from 20 to 68 (mean = 36.81, s.d. = 11.16), and included 70 males, 31 females, 33 whites, 43 blacks, and 25 Hispanics. The mean age of first psychiatric admission was 22.39 years (s.d. = 8.63), and the mean duration of illness since then was 14.41 years (s.d. = 8.95). Over the previous 18 months, 67% had been continuously in hospital; for the remainder, the mean duration of in-patient stay was 195 days. All patients were receiving psychotropic medication when surveyed. Of the full group, 72-81 subjects participated in the various cognitive tests and 42 took the random number generation task.

Design and measures

All patients suited for study on the basis of initial chart

review were interviewed on their own ward by a research psychiatrist in order to independently confirm fulfillment of DSM-III criteria for schizophrenia. They then underwent a series of evaluations deriving from clinical interview, cognitive testing, physical assessment, and intensive examination of medical records. The data collection proceeded without knowledge of patients' status on positive and negative syndrome scales, which were scored only after all measures had been conducted.

Positive-negative evaluation Patients underwent a 30–40 minute semi-structured clinical interview with the research psychiatrist, after which they were rated on the 18-item Brief Psychiatric Rating Scale (BPRS) (Overall & Gorham, 1962) and an abbreviated 12-item Psychopathology Rating Schedule (PRS) (Singh & Kay, 1975), which provides a 1–7 point rating system in parallel to the BPRS and was included because it enabled a fuller assessment of deficit features. Furthermore, it presented criteria for each dimension and for four focal points on the scale so as to enhance objectivity and reliability.

Of the 30 psychiatric parameters from these two scales, 14 served for assessment of positive and negative syndromes, as detailed elsewhere (Lindenmayer *et al.*, 1984; Opler *et al.*, 1984). The positive symptoms were delusions (from PRS), and conceptual disorganisation, hallucinatory behaviour, excitement, grandiosity, suspiciousness and hostility (from BPRS), the negative symptoms were blunted affect and emotional withdrawal (from BPRS), and poor rapport, passive-aphetic social withdrawal, difficulty in abstract thinking, lack of spontaneity and flow of conversation, and stereotyped thinking (PRS). Positive and negative syndrome scores were generated from sums of ratings on the seven items constituting the respective clusters. Each scale thereby had a range from 7 to 49. In addition, a composite positive-negative score was calculated by subtracting the negative syndrome score from the positive, thus yielding a bipolar index that ranged from +42 to -42, which reflected the degree of predominance of one syndrome over the other.

Clinical assessment. After excluding the 14 items involved in the positive-negative scales, the remaining 16 items from the BPRS and PRS served as individual measures of schizophrenic symptoms, and their sum provided an index of general psychopathology.

Based on the same clinical interview, the research psychiatrist assessed patients also on the Manifest Affect Rating Scale (MARS) to permit a more detailed inspection of affective impairment, this 15-item scale, modified from the procedure developed by Alpert & Rush (1983), is composed of 4-point severity ratings, each with descriptive anchoring points along a range from 0 (normal) to 3 (extreme pathology). Principal component analysis has identified three factors underlying the scale: emotional relatedness (mean loading=0.80), expressive mobility (0.71), and appropriateness of affect (0.60).

Cognitive testing A series of objective psychometric tests was undertaken to examine the proposition that a negative syndrome in schizophrenia relates to cognitive and neurological deficits (Andreasen & Olsen, 1982; Andreasen *et al.*, 1982) that may be of developmental origin (Lindenmayer *et al.*, 1984; Opler *et al.*, 1984). These procedures were adminis-

tered by a research psychiatrist or specially trained and supervised medical students and then scored independently by a psychologist. All involved were unaware of patients' scores on the positive-negative scales.

Intelligence was gauged with the Quick Test (QT), a recognition vocabulary measure that correlates strongly with the standard individual IQ scales (Ammons & Ammons, 1962). This technique was selected for its relative invulnerability to cognitive and performance deficits associated with psychosis (Blatt, 1959) and for its minimal demands on prolonged attention and verbal productivity.

The Memory For Designs Test (MFD) provided a standardised index of neurological dysfunction based on impaired perception of configurations and short-term visual recall (Graham & Kendall, 1960); it was chosen because of its objective scoring criteria and adjustments for age and IQ. The hand used for holding the pencil in taking this test served as indication of hand dominance.

Disturbance of attention was quantified temporally using the Span of Attention Test (SOA), which assesses the average duration that one concentrates on a routine motor task before showing signs of distractibility (Kay & Singh, 1974; Kay, 1982). The procedure also yields a measure of spontaneous psychomotor rate, calculated as the ratio of test items completed to time elapsed.

Cognitive performance was studied on a random number generation test (Salierno *et al.*, 1984), an objective treatment-sensitive measure of success in purposeful goal-directed (rather than perseverative) responding, which has been considered a fundamental adaptational deficit in schizophrenia (Shakow, 1979). Instructions call for continuous recitation, over a 60 second period, of as many numbers as possible between 1 and 10 without using any particular order. Number fluency is scored as the ratio of random numbers (i.e. discounting sequences of three or more identical or consecutive integers) to total numbers recited.

To obtain a developmentally-based assessment of cognitive processes, four tests from the Cognitive Diagnostic Battery (Kay, 1982) were administered. The Colour-Form Preference Test (CFP) examines primitive bases for perceiving relationships and pre-representational modes of thinking (Kay & Singh, 1975; Kay, 1977). It consists of a 20-item similarity judgement task wherein a standard card is matched to one of three comparison cards that are alike in colour, form, neither cue, or both. The response strategy is scored for predominance of perseveration, random response, colour concept, form concept, and multilevel concepts, which correspond to successive developmental levels up to the 7–11 year old stage. The 20-item Colour Form Representation Test (CFR) extends the CFP assessment by adding the option of match by pictorial representation, which is a more mature criterion of similarity than colour or form (Kay *et al.*, 1975). As such, it focuses on the later verbal-symbolic stages of conceptual growth. The Egocentricity of Thought Test (EOT) consists of hierarchical subtests which assess the maturity of right-left positional concepts (Kay & Singh, 1975). These depict four major phases of development identified by Piaget (1928) as crucial to cognitive and social growth: preconceptual (<age 5 years), egocentric (5–8 years), socialized (8–11 years), and

objective (>11 years). The Progressive Figure Drawing Test (PFDT) delineates the level of perceptual-motor development in patients with combined developmental and psychiatric disorders (Kay, 1980). The procedure involves drawing from copy seven simple designs that children normally master at successive ages between 2 and 6.

These four developmental measures have shown high reliability and have differentiated schizophrenics from non-psychotics and retarded patients and among various diagnostic and prognostic subgroupings of schizophrenics (Kay & Singh, 1979; Kay, 1982).

Drug side-effects. The prevalence of drug-induced EPS was measured after complete examination using two 5-point severity rating scales: Abnormal Involuntary Movement Scale (AIMS) (National Institute of Mental Health, 1974) and Extrapyramidal Rating Scale (ERS), as originated by Alpert *et al* (1978). The 10-item AIMS assesses movement disorders involving the face, mouth, extremities, and trunk. The ERS, which is similar to Borison's (1984) Scale for Recognizing Acute EPS, evaluates bradykinetic and parkinsonian drug reaction along seven dimensions: abnormal gait (stooping, loss of associated movement, shuffling, propulsion), rigidity (resistance to passive stretch, cogwheeling), tremor of extremities (including choreiform movements and pinrolling), bizarre movements (torticollis, facial grimace, tongue tremor, tics, oral movements), expression (masked facies, dysarthric speech, loss of volume, loss of inflection), restlessness (constant walking, rocking, chewing, sitting), and reduced motor activity (fatigue, slowness, weakness, inactivity).

Historical review. The following variables were generated from information in patients' medical records and the hospital's computerised storage bank: demographic characteristics (age, sex, race, ethnic group, marital status); season of birth; years of formal education; age of onset and chronicity of illness, both as determined by date of initial psychiatric admission; and total number of hospital admissions.

Family history of illness. Based on interview with the patient and scrutiny of psychosocial, developmental, and family histories from the medical records, the following categories of psychopathology in the patient's first-degree relatives were identified: schizophrenia, where the family member was admitted to hospital with this diagnosis; affective disorder, where admission had occurred for depressive, manic, or bipolar illness; major psychiatric disorder, where schizophrenic illness, major affective disorder, or unspecified mental illness had led to admission; suicide, where such was reported; alcoholism, where a history of alcohol abuse or heavy drinking had existed; and sociopathy, where the records indicated criminal behaviour resulting in arrest and prosecution. Considering the probable bias of families against acknowledging mental disorders as well as the ever present possibility of errors of omission, these data are considered minimal estimates of familial illness.

Follow-up. With the help of the hospital's computerised information system, the subjects' status as in-patients was followed up for 2½ years after their participation in the study. The total length of subsequent in-patient stay provided an index of continued need for institutional care, and it thus permitted assessment of the long-range predictive validity of positive and negative syndromes.

FIG. 1 Frequency distribution of the positive syndrome, negative syndrome, and composite positive-negative scales.

Results

Positive-negative scales

The scores on the positive, negative, and composite measures were found to be distributed fairly normally, without substantial skewness or kurtosis (Fig. 1). The positive and negative scales bore a modest but significant inter-relationship (Pearson's $r = +0.27$, $P < 0.01$), and both were strongly correlated with the composite scale ($r = +0.59$ and -0.61 respectively, $P < 0.0001$), whose scores centered around a median of -2.00 . Positive and negative scores also bore an exceptionally high relationship to the independent measure of general psychopathology ($r = 0.68$ and 0.60 respectively, $P < 0.0001$), suggesting that global severity of illness may have mediated the association between the two criterion scales. Indeed, a partial correlation which excluded the shared variance from general psychopathology revealed a significant inverse correlation between positive and negative scores ($r_{12.3} = -0.23$, $t = 2.37$, $d.f. = 98$, $P < 0.02$).

The reliability of the criterion measures was analysed using coefficient alpha for inspecting the internal consistency of the component scales. As detailed in Table I, each of the items comprising the positive and negative syndromes correlated significantly (at least $P < 0.01$) with the remaining scale total, and no perceptible gain could be achieved by discarding any item. The alpha reliability coefficients were 0.73 and 0.83 for the two scales respectively.

Correlates of positive and negative syndromes

Correlational analyses were performed to evaluate the relationships between positive-negative syndromes and 65 variables representing different spheres of functioning and different methods of assessment. Following Ferguson (1966), Pearson analysis was used for continuous normally distributed data and point biserial correlation for the discrete dichotomous variables.

Results of the simple correlations found the positive-negative dimension statistically unrelated to such demographic and historical variables as race, cultural group, sex, marital status, age at first admission, and frequency or chronicity of hospitalisation. Likewise, no significant correlations were obtained with respect to depression ratings (BPRS depression, BPRS guilt feeling, and MARS sad affective tone). Positive and negative syndromes also bore no special relationship to variables that might be linked with neurological dysfunction, namely winter birth, left hand dominance, SOA attention span, MFD organicity score, and PFDT perceptual-motor development score.

Alternatively, the analyses indicated certain similarities between patients with pronounced positive and negative features. Both syndromes correlated significantly with general wealth of psychopathology, MARS ratings of inappropriate affect and poor eye contact, and clinical ratings of tension, unco-operativeness, disorientation, impaired attention, lack of insight, disturbed volition, poor impulse control, preoccupation, and social avoidance.

The significant covariates particular to either syndrome are indicated in Table II. The positive syndrome alone was

associated with excessive noncommunicative movements, affective lability, somatic concern, anxiety, and longer duration of in-patient care in the 30 month follow-up. Of special interest was its correlation also with sociopathy in the patient's family ($P < 0.05$), in stark contrast to the relationship of negative syndrome to family history of major psychiatric disorder ($P < 0.01$). The negative scale was furthermore uniquely associated with motor retardation, slowed SOA psychomotor pace, mannerisms and posturing, lower verbal intelligence, greater cognitive developmental deficits on the CFP and EOT, and more serious affective deficiency on most MARS scales as well as the MARS total. Thus, the negative syndrome seemed to entail a deficit state encompassing the cognitive, affective, and motor spheres.

Correlations with the composite scale identified those variables that were allied specifically with one syndrome in opposition to the other. The negative pole was significantly distinguished from the positive as involving patients who had less education, showed fewer signs of anxiety and bizarre thinking, proved slower on clinical and psychometric assessments of motor function, showed greater affective deficits on 9 of the 15 MARS scales plus MARS total, exhibited more rigidity in random number generation, and presented greater cognitive developmental impairment on the CFP, CFR, and EOT.

In the foregoing analyses, there emerged a significant association between negative polarity on the composite index and two control variables: age ($r = 0.25$; $P < 0.02$) and EPS ($r = 0.26$, $P < 0.01$). This raised the possibility that the

remaining correlations might have been mediated by older age and drug side-effects. To adjust for the variance attributable to these two parameters, therefore, the data were reanalysed using second-order partial correlations. The results, included in Table II, upheld the significance of lesser education and affective deficits in characterising the negative syndrome. Differences in the cognitive and motor spheres were to some extent diluted, although negative

symptoms were still significantly correlated with motor retardation, difficulty in random number generation, and developmental dysfunction on the CFP and EOT tests. The findings in regard to genealogy were upheld, with the further observation that the negative syndrome was associated with absence of family members who have had affective disorders. Other new findings included a preponderance of males with negative features. A positive

syndrome was now associated with more previous hospital admissions, faster speech rate, and angry affective tone, whereas follow-up differences were not significant.

Multiple regression analysis

The significant correlates of the three criterion scales were subjected to multiple regression analyses to identify those parameters which principally account for the variance of the positive-negative dimension. The results (Table III) indicate the most important determinants, beyond which no significant variance is further explained.

The positive, negative and composite scales respectively yielded coefficients of multiple determination (R^2) of 0.74, 0.81, and 0.71, which converted to 0.72, 0.79, and 0.68 ($P < 0.0001$ in all cases) when adjusted for number of component variables. The positive syndrome was accounted for mainly by wealth of psychopathology and, specifically, by productive features added to the cognitive and affective spheres as unusual thinking and angry emotional tone. A family history of sociopathy also contributed significantly to the variance. The negative syndrome, in sharp contrast, was explained by impoverished cognitive and affective processes as well as deficits in social functioning and in the developmental underpinning of cognitive and social growth (EOT). In terms of genealogy, a family history of

major psychiatric disorder rather than sociopathy was a significant aspect of this syndrome.

Of particular interest for differential assessment was the composite scale, since its score delineated the two ends of the positive-negative polarity. From multiple regression analysis, unusual thought content emerged as the chief indicator of a uniquely positive syndrome. A negative syndrome, conversely, was explained by emotional unrelatedness (MARS Factor 1), older age, and cognitive deficits reflected in flawed conceptual development (CFR), poorer education, and impoverished thinking.

Discussion

Our project assessed, in a large sample of long-term schizophrenic in-patients, the significance of positive and negative syndromes in relation to a variety of parameters encompassing personal history, genealogy, epidemiology, mental status, cognitive test performance, and past and future clinical course. Preliminary analyses found the criterion scales to be reliable and normally distributed. A modest but significant correlation between scores for positive and negative syndromes suggested that these are not

independent, in consonance with the observations made by Pogue-Geile & Harrow (1984) during follow-up. When extracting the shared variance attributable to general psychopathology, however, the two syndromes had a significant inverse relationship. This supports the proposition (Andreasen & Olsen, 1982; Lindenmayer *et al*, 1984; Opler *et al*, 1984) that positive and negative symptoms are at opposite ends of a continuum, while justifying the present use of a bipolar composite index.

Multiple regression analysis demonstrated that between 71% and 81% of the total variance of the criterion measures could be explained by sets of 4–6 predictor variables representing separate dimensions. Clinically, the cluster of positive symptoms correlated with productive features involving the cognitive and affective spheres, particularly unusual thought content and inappropriate anger; correspondingly, the negative syndrome was associated with deficits in these spheres as well as in the social and motor realms. Patients with a negative profile generally emerged as socially isolated, vacuous in their affective and intellectual processes, and slow and perseverative in their responses, fitting Shakow's (1979) description of the schizophrenic with major adaptational difficulty. Contrary to Andreasen's assumption that disordered attention represents a deficit symptom of importance in distinguishing a negative syndrome (Andreasen, 1982; Andreasen & Olsen, 1982), clinical and psychometric measures found this parameter equivalently related to the positive syndrome. This result is not surprising in light of the significant association described between attentional impairment and measures of autonomic and cortical arousal on the one hand and social withdrawal on the other (Kay & Singh, 1974; Kay, 1981; Singh & Kay, 1982).

The present survey proceeded beyond concurrent functioning to examine areas not formerly probed in relation to the positive-negative dimension, notably family history of illness and prospective course of hospital treatment. Despite the likelihood that estimates of family illness were conservative, which enhances the risk of Type II error, genealogy appeared to be highly relevant. Thus, a positive syndrome was reliably associated with sociopathy in first-degree relatives, whereas a negative syndrome was linked to a family record of major psychiatric illness but absence of affective disorder.

In terms of the course of illness, a positive syndrome seemed to be anticipated by a greater number of prior hospital admissions and to portend more time subsequently spent as an in-patient, perhaps suggesting stormy episodes with decreased tractability in the more chronic phase. These

observations, however, were not independent of covariance with age and EPS. The finding that older patients tended to rate higher on negative features could signify enhanced representation of these symptoms in later years as the florid manifestations subside, although such an interpretation can be confirmed only by longitudinal study. As moderating variables, age and EPS were shown to have some mitigating effect on the findings in regard to motor activity and cognition, but overall did not obviate the key distinctions between positive and negative syndromes: differences were upheld on the historical, genealogical, and affective dimensions, and conclusions regarding clinical, cognitive, and motor functioning were not substantially modified. Similarly, the control variables, such as ethnic origin and chronicity of illness, had no significant bearing on any of the positive-negative indexes.

The data on the negative syndrome supported the hypothesis of premorbid impairment in cognitive maturation. Patients scoring higher on this dimension had achieved less education and were more impoverished in thought, as judged by independent clinical and psychometric procedures. On cognitive developmental tests they showed more fundamental deficiency in elementary conceptual and representational modes of thought and in the flexible use of socialised and objective perspectives. Poorer premorbid functioning by schizophrenic patients with negative features has been documented elsewhere in regard to schooling (Andreasen & Olsen, 1982; Lindenmayer *et al*, 1984; Opler *et al*, 1984; Pogue-Geile & Harrow, 1984), social relationships (Andreasen & Olsen, 1982; Pogue-Geile & Harrow, 1984), and occupational history (Andreasen & Olsen, 1982; Lindenmayer *et al*, 1984). A recent study of Pogue-Geile & Harrow (1984) indicated that "these patterns may better characterise male than female schizophrenic patients", and an independent meta-analysis by Aylward *et al* (1984) revealed that premorbid intellectual deficits are also more prevalent among males and forebode poorer heterosexual adjustment, worse clinical functioning, and sustained deficits. These observations give meaning to our finding that relate negative syndrome to lower IQ and, after adjusting for age and EPS, to male gender.

Cumulatively, these data underscore the importance of a biodevelopmental perspective on the aetiology of schizophrenia. For a subgroup characterised by a predominantly negative syndrome, it appears that pre-existing developmental failures foreshadow lifelong multimodal deficits (cf. Aylward *et al*, 1984; Pogue-Geile & Harrow, 1984). From a different perspective, high-risk studies (Marcus *et al*, 1981; Parnas *et al*, 1982; Walker & Emory, 1983)

have implicated early developmental dysfunctions as harbingers of schizophrenia and, in keeping with family and cross-fostering studies (Gottesman & Shields, 1976), have suggested a genetically mediated process. The current work, congruent with this model, has identified family loading and gender as important determinants of how the schizophrenic condition will be manifested in the chronic phase.

The proposition that negative features are associated with structural organic deficits (Crow, 1980b; Andreasen *et al.*, 1982; Seidman, 1983; Weinberger & Wyatt, 1983) was not supported in the present study. Although some of the correlations approached significance at the $P < 0.10$ level, the negative syndrome showed no clear-cut relationship to tests of perceptual-motor development (PFDT), neurological soft signs (MFD), or disturbed attention (SOA). Indirect evidence from hand dominance (Andreasen & Olsen, 1982) and season of birth (Opler *et al.*, 1984; Opler & Kay, 1985) was also not substantiated by this larger scale study.

Further investigation is needed to confirm and extend our findings. Of special importance is assessment of the stability of the positive-negative dimension across time and in relation to neuroleptic drugs. For example, the question of whether the syndromes

represent a temporary state or enduring trait has not yet been resolved. Equally compelling is the possibility of their being iatrogenic transitional or end states. Thus, it is conceivable that 'positive' schizophrenic patients are potential drug responders still in a preliminary stage of chemotherapy or not under the ideally suited neuroleptic, whereas those with a predominantly negative syndrome are the residual types who have remained deficit-ridden after the florid presentation has been controlled by medication. Since the significance of positive and negative syndromes under drug-free conditions has still to be explored, the generality of our findings remains in question. Finally, we must point out that the inclusion of 65 variables, even in a large sample study, increases the possibility of some spurious results. Although many more significant coefficients were obtained than would be expected by chance, and a distinctive pattern emerged which differentiated the positive and negative syndromes, caution must be exercised in interpreting the importance of any individual variable.

Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, pheochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices.** **Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 10 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.

TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept. Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients. Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes. Most patients can be controlled with an injection at intervals of 3 weeks or more! Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

FROM CLINIC...

...TO COMMUNITY

CLOPIXOL®

zuclopenthixol dihydrochloride/zuclopenthixol decanoate

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses.

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses.

Children Not recommended.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics.

with Parkinsonism, severe arteriosclerosis, senile confusion states, serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. Pl. Nos 0458/0027, 0028, 0029. PA Nos 115/5/3, 4, 6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.

Children Not recommended.

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation

or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.

Package quantities & NHS price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. Pl. Nos 0458/0017, 0041. PA Nos 115/5/1, 5, 7.

A Haven for the Severely Disabled Within the Context of a Comprehensive Psychiatric Community Service

J. K. WING and R. FURLONG

The priorities accorded severely disabled or disturbed long-stay patients in Regional and District planning strategies vary enormously. A scheme to cater for the needs of this group is described. The scheme includes: non-stigmatising housing; a domestic regime, daytime occupation and leisure activities offering forms of enabling and caring that foster the highest possible levels of functioning; a secure home; private and peaceful outdoor space; and graduated steps towards independence that allow for the possibility of relapse. The central concept is the establishment of a Community for people with severe difficulties in making social contacts. The importance of integrating the scheme into a comprehensive District psychiatric service is emphasised.

The term 'asylum' has both benevolent and pejorative connotations, and motives for establishing sheltered institutions have usually been mixed. Lunatic asylums were established both for humanitarian reasons and because the community at large was frightened by manifestation of insanity and understood that protection worked both ways. The extraordinary strength of this combined motivation is evident from the volume of resources put into building and maintaining the county asylums. They still stand: a visible index of the capital and revenue needed to create a new system of care for mentally afflicted minorities, and a challenge for our own time. In this paper we discuss, in the context of evidence that the build-up of 'community' alternatives for the long-term mentally ill is at best half-hearted compared with the speed of rundown of the hospitals (Social Services Committee, 1985), what is to be the fate of people who need to be offered a haven.

Planning for the needs of the disabled

The concept of 'need' is based on that of 'social disablement', which in turn is derived from a concept of normal social functioning and expected quality of life. 'Disablement' is defined in terms of the degree to which an individual falls short of the level of performance that is generally expected within a given society, as interpreted by the afflicted individual or those closely connected with him or her. The more severe and general the departure from 'normal' social functioning, the more likely is agreement to be reached that social disablement is present and, potentially, that help is needed.

A full analysis of the concept of need requires consideration at three levels:

- (a) the causes of social disablement, which can be summarised under the headings of intrinsic impairment, social disadvantage and personal distress or demoralisation.
- (b) specific, effective and acceptable forms of care (including treatment, training, rehabilitation, shelter, security, and welfare) for problems defined under (a)
- (c) the service that will prevent, ameliorate or contain these problems, through the 'delivery' of specific, acceptable and economic forms of care (Wing, 1972).

The application of this kind of analysis across a district allows comprehensive 'bottom-up' planning, based on the aggregated needs of individuals. Within a geographically based national health service, planning and provision should be based on three principles—identification of individuals in need through the application of epidemiological knowledge, provision of a wide variety of service components to deliver packages of treatment or care in accordance with fluctuating need; and organisation and management that ensures integration and continuity in a system that could otherwise become fragmented (Wing, 1978).

Systematic surveys provide data that demonstrate needs for a wide variety of methods of help, and therefore a wide variety of services. The latter can be illustrated by the analogy of three stairways with landings (see Table I), each representing a major functional area of everyday life: occupational, residential and recreational. Disability in one of these areas does not necessarily (or even usually) imply disability in all. This analogy provides a reminder of the interaction between the functions of services

TABLE I
The stairway analogy. Service and needs can be likened to three stairways (columns) with landings (horizontal lines)

<i>Dependency</i>	<i>Occupation</i>	<i>Residence</i>	<i>Recreation</i>
Low	Can occupy self	Maintains own home	Own and shared activities
	Sheltered paid work	Supervised flat or lodging	Accompanied to public amenities
Moderate	Industrial therapy unit	Group home	Reserved hours e.g. at swimming pool
	Occupational therapy unit	Staffed hostel	Restaurant and social club
	High dependency day unit	High dependency hostel	Private grounds for exercise
		Sheltered Community	
High		Secure Unit	

N.B. An individual can be highly dependent in all three areas but living at home with relatives.

(movement up and down, respite on the landings, and the use of artificial aids to help people climb) and their structures, which should be subordinate to function. Towards the top of each of the stairways, individuals are able to make use of the options available and to help chart their own paths through the system. We are concerned in this paper with those with high dependency needs, who remain on the lower steps in spite of prolonged efforts to decrease the severity of their social disablement. Unless the rest of the service is in place, however, the chances of their moving towards greater independence, or of moving down according to need (rather than precipitously), will be substantially fewer.

The high-dependency group

The term 'dependency' is non-specific and provides no guidance about requirements for particular forms of service; it simply indicates a high all-round level of need for care which has hitherto usually been equated with a need for long-term residence in hospital. There are many causes of high dependency, and systematic surveys have always revealed complex causal patterns of multiple impairments, social disadvantages and adverse personal reactions. Because each individual's pattern is unique (and

often changes over time), each needs an individually oriented programme of care.

The characteristics of patients (other than those with severe mental retardation or dementia) who have recently had hospital stays of over one year, in spite of current trends to avoid such long stays, can be used to describe the wider group of people with which we are concerned (Mann & Cree, 1976). Chief among the common factors is a record of contact that stretches back long before admission. Very few have put down roots in an outside community, have recently been employed, are married and in touch with their husbands or wives, or have a home that can accept them (although most have relatives somewhere). Most are middle-aged to elderly.

The most common diagnosis is schizophrenia, but up to half have other conditions such as short-cycle manic-depressive psychoses, chronic depression, or personality disorders. Many patients have multiple disabilities such as epilepsy, mental retardation, brain damage, sensory deficits, and neurological disorders. Physical diseases of all kinds are common, and have a high frequency in the elderly. In many cases, social disablement has remained severe and intractable in spite of the fact that the quality of assessment and care has been as good as possible. This is mainly due to five factors which complicate treatment and set limits to the degree of independence that can be achieved:

- (a) risk of harm to self or others
- (b) unpredictability of behaviour and liability to relapse
- (c) poor motivation and capacity for self-management or performance of social roles
- (d) lack of insight
- (e) low public acceptability.

These factors interact with each other. Each may be assessed differently, in any particular case, by a stranger, a caring relative, a member of staff or an afflicted individual. Staff who act as gatekeepers to services have to try to assess all of these factors and allocate a degree of priority to each. The less experienced and skilled the observer, and the shorter the acquaintance with a chronically afflicted individual, the less visible many of the problems appear to be.

Those people with high dependency needs tend to present problems that are complicated by several of the five factors, acting either together or within short intervals of one another. Dangerousness is complicated by unpredictability and by lack of insight, or by a degree of insight that is sufficient to control behaviour in one setting (e.g. an out-patient clinic or at a domiciliary visit) where compulsory action could be taken, but not in another (e.g. at home with relatives) where no such power exists.

Self-harm not only includes immediate self-injury or suicide but may arise from poor self-management by reason of neglect of physical health (nutrition, personal hygiene, exercise, smoking, alcohol, exposure to cold or other dangers), and from lack of awareness of the value of medication or of attendance at a day centre. A complicating factor is public hostility due to socially embarrassing behaviour or to deterioration in the environment; for example, when a flat falls into disrepair, begins to smell and constitutes a fire hazard. A lack of motivation makes it impossible for some disabled people to imagine how problems can be overcome and leads to an apathetic acceptance of a drift into destitution (Lamb, 1980; Leach & Wing, 1980). A less obvious consequence is that the individual becomes easily exploitable.

These extremes of behaviour occur much less frequently in a well regulated and protected setting. Hence, characteristics of the environment are an important part of treatment. The question is one of how far caring environments can be prescribed for people whose lifestyle is gradually deteriorating through apathy, in a way that is unacceptable to their relatives and to the public in general. This lack of concern for one's own welfare is similar to that of long-term residents in old-fashioned mental hospitals, who were either indifferent to discharge or actively wished to stay, even when their intrinsic

impairments were not severe. Such gradually acquired negative attitudes to discharge from hospital ('institutionalism') were hypothesized to be part of a process of development of adverse self-attitudes and decreased motivation that can occur in any setting characterised by 'social poverty', and is potentiated by the cognitive deficits of several psychiatric disorders (Wing, 1964; Wing & Brown, 1970). The process is still occurring in socially impoverished 'community' settings, now that most of those at risk no longer become long-stay hospital inmates. The most readily influenced of the environmental factors, both for good and harm, is the quality of social environment provided.

The size of the high-dependency group

There is still a sizeable group of people who need security, protection or shelter in two or more of the three major areas of life, whether or not that protection is currently being offered or taken up. Calculating the size of need by extrapolating from hospital bed occupancy is problematic, because some long-term in-patients could be discharged if lower dependency facilities existed elsewhere, and some of those 'in the community' would have a better prospect of a reasonable quality of life if they were in a sheltered community.

The statistics of rundown of the 'old' long-stay group and build-up of the 'new' are best summarised in Robertson's note of guidance to regional statisticians (1981). His higher estimate (which most closely fits the trends) suggests that, if there are no radical changes in service practice, an average health district will be using 140 in-patient beds per 100 000 inhabitants by the end of 1991, of whom 80 would have stayed for a year or more. For those without a diagnosis of dementia, the long-stay rate would be 53 per 100 000 (Robertson, 1981; Wing, 1986).

The survey by Mann & Cree (1976) suggested that 34% of long-stay (1-3 years) in-patients under 65 needed further hospital care, 25% needed 'hospital-hostels', and 32% needed other types of supervised residence. One hospital in each health region in England and Wales was visited, but in nearly all cases the alternative accommodation did not exist. Dependency becomes substantially higher the longer people stay and the older they get.

Two factors, acting in opposite directions, could upset any estimate of numbers. On the one hand, the discharge of long-stay patients might accelerate; on the other, a recognition that adequate non-hospital facilities were not being provided might lead to a greater use of long-term hospital care. Neither contingency is predictable with any confidence, but

such calculations are in any case irrelevant to the questions that interest us, which are concerned with meeting need wherever it occurs.

Surveys of day attenders, hostel and group home residents in Camberwell have not demonstrated any substantial unmet need for long-term high dependency care, but the local services are generally well above average and the results cannot be regarded as representative (Wykes *et al.*, 1982). On the other hand, surveys of families known to organisations such as the National Schizophrenia Fellowship (Creer & Wing, 1974) and of single homeless people (Leach & Wing, 1980) have shown that an unmet need for a good quality of sheltered environment is not confined to hospital in-patients. Register data suggest that some Health Districts, particularly those with a declining population near the centre of conurbations, are likely to have high rates, while Districts in attractive areas with increasing populations will have low rates (Gibbons *et al.*, 1984).

Sociodemographic indices such as age, social isolation, poverty and ethnicity have important implications, as have geographical factors and local traditions in the provision of services. There can be no such thing as a national or even a regional norm. Our best estimate of 50 places per 100 000 population for an 'average' District is not intended to be taken as more than a starting point for better-informed local calculations. In particular, we urge that the fact that some (usually privileged) Districts appear to have a low order of need should not uncritically be used to set a standard for the whole country.

Appropriate caring environments

Large-C and small-c communities

The term 'community' is often used loosely, but two particular uses are common. The word is often used to create an image of a well-integrated village or neighbourhood whose residents know and care for each other, where few inhabitants feel isolated or remote from help should they need it. This would be a 'large-C' Community. 'Small-c' communities lack this cohesion. Examples are inner city areas, which are notoriously deficient in these respects. Even the residents of affluent suburbs may be preoccupied with material standards that demand a conventional normality. Moreover, rural villages may fall short of romantic expectation. A recent study of attitudes towards mentally retarded children showed that urban mothers were more likely to be favourable than village mothers (Sinson, 1985). Neighbours do not always help or even sympathise with the problems of families with a mentally disabled member. Formal systems of service delivery developed

"because the informal networks of mutual aid in local communities were manifestly incapable of meeting the kinds of personal need which arise in complex industrial societies" (Pincus, 1982). Public attitudes, as the last White Paper on services for the mentally ill pointed out, need to become more favourable before it becomes feasible to give sufficient spending priority to them (DHSS, 1975).

We share the view commonly held throughout the caring professions that severely disabled and disturbed people should, as far as possible, be helped to use public amenities and facilities, to live in ordinary houses in ordinary streets, to undertake the same activities, and to receive the same personal support from friends, relatives and neighbours as those who are physically and mentally fit. However, implicit in some influential formulations of this position is the assumption that virtually everyone, no matter how severely afflicted, can achieve an acceptable integration while dispersed in 'the community'. 'The institution' (i.e. any structure that implies a degree of segregation) is thus seen as inherently harmful.

The term 'normalisation' is often used to express the underlying thrust of this argument. From this point of view, to begin with an analysis of the causes of social disablement, particularly if this includes the concept of physical or mental impairment, is regarded as counter-productive. The term has most frequently been used in discussions of services for the mentally handicapped, and is now appearing in plans for long-term residents of mental illness hospitals. The danger in both instances is that the underlying good intention may be thwarted by the fact that becoming 'as normal as possible' (a more modest but more realistic formulation) depends on particular kinds of help from people and agencies familiar with the varied causes of social disablement, and therefore with specific needs. Trying to apply a general standard of 'normality' without starting from the concept of impairment can lead, in spite of the best intentions, to a drop in the quality of life of disabled people.

A different use of the term 'Community', explicitly with a large C, is to denote a group of people coming together because of a shared interest, in order to pursue through personal relationships and the exercise of special skills some common purpose—moral, artistic, political, or therapeutic. The Steiner Communities, for example, represent the first and last of these purposes. Few people who have visited them would deny the sense of real Community, even for those residents who are so disabled as to be incapable of understanding the full meaning of the word, and for whom it must be partially artificial. This sense is created by the beauty and simplicity of the buildings and surroundings, the shared

motivation of the staff, the significance given to each activity of daily living, and the evident quality of life of the residents. Nevertheless, each Community is an institution. There is also an inherent element of segregation. Moreover, such charitable organisations do not accept what has hitherto been the final responsibility of the National Health Service—not to select. (It must be said that the NHS does not always accept this responsibility nowadays.) People who are disruptive or socially impaired are no more welcome than they are in most local authority hostels.

However, the success of the Steiner Communities demonstrates that a semi-detached house in an urban street is not the only alternative to a hospital ward, particularly for those people who cannot (and do not) use community amenities and who are unable to create any sense of Community around themselves because their social skills (in spite of adequate efforts at training) are lacking.

Open versus custodial care

Erving Goffman (1961) introduced the concept of the 'total institution'. He argued that American state mental hospitals in the 1950s resembled other segregated communities in which inmates were isolated from the everyday life of the community such as prisons, orphanages, concentration camps, and even battleships at sea. The staff and inmates had fundamentally different points of view and perceived each other in terms of narrow, hostile stereotypes. Inmates slept, worked and played in one place, and an overall rational plan guided all behaviour. Even the smallest details, such as when an inmate should bath or go to bed, were decided by authority. Inmates were no longer looked upon as fathers, or employees, or customers, and their abilities to play social roles atrophied from misuse.

Although British mental hospitals, even then, did not much resemble this picture (for a comparison

with an American county hospital see Wing & Brown, 1970), an image of hospitals as globally and inherently custodial has stuck and the term 'institution' is now, in this context, almost exclusively pejorative. Table II illustrates the two extremes of custodial and open systems of care. Attempts to measure the degree of restrictiveness indicate substantial variation and overlap within and between care settings. Custodial care cannot be equated with hospital wards, nor open care with non-hospital alternatives (Rawlings, 1985a,b; Ryan, 1979; Wykes *et al.*, (1982). Moreover, the term 'restrictiveness', whatever the setting, carries a connotation of arbitrary authority that may be unjustified (Hewett, 1979). The proper question, in respect of particular individuals, is whether help is being given that will reduce the causes of social disablement to the minimum possible level and maintain them there. If so, needs for asylum functions will be met with the minimum segregation and dependence, always taking into account that some people need solitude more than others.

The haven concept

The idea of Haven Communities arose from two kinds of experience. One was with a hostel-ward ('hospital-hostel' or 'ward in a house') set up at the Maudsley hospital for people from Camberwell under the age of 65 who had been living in hospital wards for 1–7 years (Garety & Morris, 1984; Wing & Hailey, 1972; Wykes, 1982). The results suggested that virtually all such people could benefit from the greater personal attention and gradual introduction to responsibility that such an environment made possible. A subsequent, better controlled, evaluation of a hostel-ward in Manchester, and an uncontrolled study of one in Southampton, confirmed most of these findings (Gibbons, 1986; Goldberg *et al.*, 1985). These two hostel-wards were off-campus, and hence had to be selective; some other unit would still be

TABLE II
Custodial and open care

<i>Characteristic</i>	<i>Custodial settings</i>	<i>Open settings</i>
Power and staff attitudes	Oligarchic, authoritarian and arbitrary	Democratic; team working to clear guidelines
Boundaries	Impermeable, whether visible or not	Human scale; flexible security
Stigma	Concentrated	Diluted
Outside influences	Easily evaded; occasional scandals	Open access; elected committee, inspectorate
Milieu	Social poverty; pauperism; inactivity; unnecessary dependence	Socially rich; local standards; choice for growth

required for the most disturbed. The second experience was that of a mental hospital that (even in the late 1950s) provided a social environment that was markedly above average in quality, and where the greatest priority and prestige was accorded the long-stay wards (Freudenberg, 1970). From the statistics given earlier, it is clear that several such houses would be needed in many Health Districts.

Though there are a few exceptions, non-NHS alternatives currently tend to reject the most severely disabled and disturbed people, and therefore do not come into consideration. We rule out the use of District General Hospitals as sites for communal living; they are busy, crowded, and lacking in space and opportunities for occupation and recreation. The orientation of the wards (which are not, in any case, satisfactory living environments) is not conducive to gradual healing over years; and often there is not a tree or blade of grass to be seen.

This leaves three possibilities: use of part of a mental hospital site, if conveniently situated near the District it serves and managerially independent; conversion of some other equally convenient site within the District; and dispersal of the component elements throughout the District. The first two of these are in most respects similar.

The haven project

An opportunity to set up a first Haven Community has arisen in the NE Thames Health Region as part of plans to close the large Friern Hospital and to use part of the site to serve the borough and Health District of Haringey. The underlying principles described below could be adapted to other situations.

Candidates for the Haven will be adult Haringey residents of all ages (excluding those with severe mental retardation, dementia or primary addictions) who have spent more than one but less than fifteen years in hospital, are chronically mentally disabled or disturbed in behaviour, and are seriously impaired in ability to care for themselves. Initially, 50 places will be provided to serve West Haringey (population 110 000).

Range and style of housing

Based on a survey of Friern patients eligible for the Haven Community, we estimate that a core group of four houses will be needed for those needing most care and shelter. One house (or hostel) with twelve residents will serve as the heart and resource centre of the Community. It will provide for patients who need frequent short readmissions and younger persistently disturbed people. The three other core houses will

each have six residents: one will cater for the long-term severely disabled with physical problems such as severe epilepsy or Huntington's Chorea, another will provide treatment and containment for those who tend, if unsupervised, to wander without regard to common danger, and the third will provide for frail elderly people with long-standing functional psychiatric disorders. The remaining 20 residents will live in a range of houses and flatlets with a lower degree of supervision. They will provide a gently graduated range of facilities, so that maximum independence can be developed and maintained in those whose disorders necessitate lengthy care, e.g. those with unpredictable behaviour, those detained on Home Office regulations and those with major dependency problems.

Staff offices, an occupational therapy store, a visitors' room, and recreation rooms with a beverage bar for the whole Community will be provided adjacent to the central house. Staff will use the same accommodation as residents. Each resident will have a personal bed-sitting room, and each house will have the usual domestic offices and living arrangements. Residents will participate in running their own houses, including cooking, cleaning and repairs. Each house will be allocated a weekly or monthly budget, so that the responsibilities of domestic management can gradually be acquired.

The choice of site for this group of houses is important. It should be clearly separated from hospital buildings, and have its own identity and access from a public road. Fortunately, the Halliwick part of the Friern estate provides a most attractive area for this development, and recently built local housing is pleasant enough to serve as model so that the Haven can merge into the background of the community. All houses could readily be converted for other uses if, in due course, they became redundant.

In addition, linked to the Haven but scattered among the local housing estates would be peripheral group homes and supervised apartments, set up in association with the local authority or charitable organisations, in order to provide for graduates who still need various degrees of Haven support and also for people who are a rung or two up the ladder but highly vulnerable to relapse. This arrangement has proved successful in connection with the first hostel-ward at the Maudsley Hospital (Wykes, 1982).

Administration

The Community would be administered from the central hostel and offices, with a single manager who would be part of the multi-disciplinary team

(including nursing, medical, occupational therapists, psychology and social work staff) responsible for running the Haven. The central hostel would be staffed day and night by trained and experienced staff, who would also be available to help when problems arose elsewhere in the Community. The other three core houses would also need some cover at night. Day-to-day running would be left to the houses themselves. The lower dependency houses would function with the help of a housekeeper during daytime hours and call buttons for emergencies at night or weekends. Staff would be aware of situations where problems could arise, and organise their rounds accordingly.

Since the Haven Community will be serving a designated population it is essential that it has clearly established links with other parts of the district services. In particular, it must provide an integrated service with those units that form steps, on the three 'stairways' described earlier, that are within reach of Haven members. Rehabilitation for this group consists of numerous small advances separated by pauses for consolidation. Continuity of care is therefore vital. Ease of movement into and out of the Community is essential. Haven staff would all take part in off-site activities both in following up and supporting ex-members and in developing links with people who might need their help in future. Close contact would therefore be kept with families, relatives' organisations and other community groups, so that early intervention can be achieved when necessary. Co-ordination will also be required with acute hospital services, psychogeriatric facilities, and primary and secondary medical services. Staff will be selected because of their interest in and aptitude for creating a living Community in partnership with residents and families. Because of its innovative aspects, the Haven Community would be an ideal setting for staff training.

Occupation and day care

In part, Haven members will be occupied within the Community, and domestic experience is part of the function of the houses. Those who have reached retiring age may not wish to engage in many formal activities. However, the exercise of all one's faculties is a necessary condition of physical and mental health, and Community members will be given a choice of opportunities. The Health District will be served by industrial and occupational day units, both in and away from the Friern site, which will facilitate continuity and flexibility of occupation for those members who can make use of these opportunities. A market garden is also planned. At the other end of

the spectrum, an intensive day-care facility will be required for those people who need a degree of security, usually during a prolonged day-care period from breakfast to supper time, including weekends. Disturbed behaviour is usually less evident in the later evening and at night. A small unit will be attached to the hostel to cater for this need, and to provide more organised domestic re-training to enable members to retain their daily living skills.

A further type of provision is also being considered. As part of the outreach links to the wider community, it is proposed to set up a charitable trust in association with local church and citizens groups to establish and administer a community centre that will serve a membership drawn from the local neighbourhood, Haven residents, relatives' organisations and staff. The centre would include meeting, recreation and dining rooms, a kitchen and bar, and sheltered workshops, such as printing and upholstery, that could provide some revenue and be of general use. In due course, an arts centre would be an appropriate addition.

Opportunities for recreation will also be needed by people who cannot make use of public amenities or who, because of their slow or odd or indecisive behaviour, may not be welcomed. There will be space where people can wander in private and where oddities of gesture or demeanour will not incur arrest or public ridicule. Ideally, some amenities would be created that were shared with the locality.

The Friern estate

The fate of the large Friern estate has yet to be decided, although approximately one third (known as present as the Halliwick site) is likely to be retained for Haringey District Health Authority and 'supra-District' functions. The rest will probably be sold and, in view of the Secretary of State's assurance (*The Times*, 17 February, 1986), the money thus raised will be earmarked for the further development of services for the mentally ill. The main hospital building is in poor repair, and it is difficult to see what purpose most of it could serve once better alternatives had been provided. The Regional Health Authority has given assurance that priority will be given to the development of services for the most severely and chronically disabled—including the Haven Community for which funds have already been allocated. We strongly support this point of view, and would like to see it adopted by other Health Regions.

The opportunities offered for improving the quality of life of mentally disabled people by the redevelopment of the Friern estate are tremendous, and it would be a tragedy if they were missed. The

overriding principle of planning should be to regard the site as a precious public amenity and to open its parkland to wider community use. Any commercial development should be limited to the provision of facilities that would attract the public onto the site. Possibilities include a centre for indoor and outdoor sports and leisure activities, a shopping complex, an arts centre, and a restaurant. Some industrial development might be considered if this included provision for sheltered work. The scale of any new building should not take up much more space than the present main hospital complex. The central administrative block, which has a certain Victorian charm and is listed Grade II, should be preserved and converted for other uses, including a museum and archive. However, there would be room for a small housing estate, which could incorporate some houses for staff and ex-patients. Local new housing is already of a good standard and appearance. Imagination and a coherent architectural plan is required to combine visual attractiveness with convenience of access and use.

The area set aside for health services would include substantial private areas, but there is no reason why the public should not use paths that crossed it. Similarly, members of the Haven Community and other users of the Halliwick site would be able to benefit from the facilities in 'Friern Barnet Park' as members of the public in their own right.

Hospitals such as Friern Barnet, which are in the middle of busy urban areas, have achieved over the years a status in the neighbourhood that is not entirely unfavourable to their residents. The sight of patients using local shops and pubs and strolling round local streets is familiar, generally accepted and, in certain respects, welcomed. Such stigma as is due to the inappropriate attribution of characteristics such as unpredictability and violence is likely to be diluted by bringing 'Community' and 'community' together in the way we suggest. The sympathies of those who are able to appreciate something of the problems caused by mental disablement could be engaged. On the other hand, geographical dispersal in small units is most unlikely to dilute the stigma that is aroused by truly socially embarrassing or unacceptable behaviour and could actually provide a series of nuclei around which stigma became concentrated.

A different kind of solution to the one proposed here has been suggested for the Claybury Hospital site, which is also in the NE Thames Region (*Architectural Review*, January 1986; Burrell, 1985). The proposal is to transform "the existing hospitals into urban quarters" that are fully integrated into the surrounding area. Ward blocks will be converted

into shared flats and houses. We welcome this idea, and hope that there will be competition throughout the country to develop imaginative and practical solutions to the varied planning problems presented in different localities.

The context of district planning

The three principles of Health District planning described earlier can be applied to the case of any particular group of people in need. The first principle is identification of individuals living within a defined geographical area of responsibility who are in need of various forms of care. This includes people who have only transient geographical links, or who drift from one place to another, never establishing 'residential rights' in any one location. Resources should be allocated to Health Districts and to local authorities on the basis of local requirement, including the needs of those who are homeless. We argue that responsibility for the most severely disabled and disturbed group (of which those we have discussed form a substantial part) should be given high priority rather than left as a residual group to be provided for only when all other services are in place. This means, as the Social Services Committee pointed out (1985), that the budget currently available to this group should be identified and should not be used for any other purpose unless there is clearly a surplus. This is most unlikely to be the case during the next decade or two.

The second principle—flexible, comprehensive and varied service provision—means that members of a Haven Community will have the opportunity to move towards independence by easy steps and stages as and when improvement occurs. By the same token, access down the 'stairways' to haven membership will also be simplified.

The third principle—sound management and organisation—ensures the maximum degree of autonomy for individual components (such as the Haven houses) of a District service, while maintaining an overall operating policy that ensures continuity of care and smooth working relationships between all units. Good administration will also ensure that staff numbers and staff training are appropriate to cope with the levels of difficulty likely to be encountered. Ideally, one executive body, with an identified budget, should eventually be made responsible for co-ordinating all care for the mentally disabled. For the moment, the District Health Authority should be regarded as the lead authority and given the duty of initiating and maintaining a co-ordinated service that will meet the needs of the population it serves.

Evaluation

The NE Thames Regional Health Authority has had the foresight to set up the Mental Health Services Evaluation Committee and to support a small research team for assessment of psychiatric services based at Friern, under the honorary directorship or Dr Julian Leff. The value of the Haven Community

will be independently assessed in comparison with that of other, more dispersed, core and cluster schemes and in the context of more general evaluation of the rundown of Friern and Claybury hospitals and the build-up of various patterns of new community services, particularly in the boroughs of Islington and Haringey. It is greatly to be hoped that other Health Regions will follow this example.

Providing Information to Relatives About Schizophrenia: Some Comments

N. TARRIER and C. BARROWCLOUGH

There has recently been an increased interest in providing relatives of schizophrenic patients with information about the illness and how to manage the patient at home, due partly to the development of psychosocial intervention programmes (which frequently include an educational component) and a consumer demand for such information in an era of community care. Studies which describe the effects of such educational programmes are reviewed, and two different models of information acquisition are contrasted. These models have different implications, in terms of outcome measures, on how educational programmes should be evaluated. Guidelines are offered for practitioners wishing to give information to relatives.

A general rise in public interest in health and in desire for knowledge about illness (Fry, 1984) has coincided with increased recognition of the importance of social factors in the course of schizophrenia, and with the beginning of prophylactic psychosocial interventions to try to reduce relapse rates. The development of expressed emotion (EE) ratings (Vaughn & Leff, 1976a) has allowed a dimension of social stress to be operationalised and quantified, and its relationship with post-discharge relapse rates to be investigated. The finding that patients returning to a relative rated as showing high EE have higher relapse rates than those discharged to low-EE homes has been consistently reported (Brown *et al*, 1972; Vaughn & Leff, 1976b; Vaughn *et al*, 1984). These results gave impetus to attempts to reduce the risk of relapse by psychological intervention (see Barrowclough & Tarrier (1984) for a review), but a lengthy training period is required for the administration of the Camberwell Family Interview (CFI) and for rating the audiotaped interviews on which the EE concept is based. Moreover, the amount of time required to administer and rate the CFI may restrict its clinical use.

An integral part of the intervention process has been a knowledge or information component, by which patients are provided with information about the diagnosis, symptomatology, aetiology, treatment, and course of schizophrenia (e.g. Leff *et al*, 1982; Falloon *et al*, 1982; Anderson *et al*, 1981), and this might be integrated more easily into clinical practice. However, this necessitates further investigation into how information about schizophrenia might best be presented to relatives and patients, and what effect this information has on them.

The burden on relatives caring for a person with schizophrenia is well known (Creer & Wing, 1974), yet many patients with significant disability have little contact with psychiatric services (Johnstone *et al*, 1984), and in many cases families and relatives are the real primary care rehabilitative agents for the chronic patient. With the increased impetus towards community-based services, families are more likely to be taking on this role, often by default, and at a time when other environmental factors (e.g. economic trends and unemployment) probably make this role increasingly difficult (Barrowclough *et al*, 1984). However, relatives are often not actively supported in this work (Lamb & Oliphant, 1978), and may even be blamed for the illness itself (Appleton, 1974). How information about the nature, course, treatment, and management of schizophrenia could assist relatives to help to rehabilitate patients needs to be examined.

Presentation of content of the information

In different studies, the method of delivery of such information has varied from lecture-style presentations (Leff *et al*, 1982) to combining individual presentations with written material (Falloon *et al*, 1982) and video presentations (Smith, 1984). Information has been presented to individual families (Leff *et al*, 1982; Falloon *et al*, 1982), to groups of families (Smith, 1984), in a workshop format (Anderson *et al*, 1981), and by post (Smith, 1984). However, the general lack of evaluation of different modes of presentation led Smith to comment that "the means of delivery has tended to be fairly arbitrary, seemingly based on the unwritten assumption that information is information irrespective of how it is given".

While the effectiveness of different modes of presentation

needs further investigation, the accessibility of the information given to the recipient must be assured, and not assumed. For example, when a reading analysis (Flesch, 1948) was performed on the booklet used in the Falloon *et al.* (1982) study, it was found that only the upper 24% of the population would be able to comprehend it, functioning at their highest reading level. This is not a criticism of the latter study; Falloon *et al.* recognised that some patients and relatives were unable to read the handouts, and the chief communication modes used were oral presentation and discussion (McGill *et al.*, 1983). Moreover, the educational sessions were part of an intensive family intervention. The issue of readability of information becomes more pertinent in cases where brief educational interventions are utilised, or where there is heavy reliance on relatives utilising written material (e.g. Smith, 1984).

Since research into doctor-patient communication suggests that only a few items of information can be retained by recipients (Ley, 1979), it may be necessary to be more selective in the information put over. It is therefore important to identify the relevant aspects of schizophrenia for this purpose.

Models of information-giving

The rationale for providing information can be argued from two points of view. Firstly, from a practical standpoint: that such information from health care professionals will either alleviate an undesirable state (e.g. anxiety, confusion, or distress) or encourage positive and desirable behaviour (e.g. health-promoting behaviour or compliance with medical treatment) on the part of the recipient. Secondly, from a moral basis: that the consumer or recipient should, as a basic right, have access to information if he desires it, and in a form that he will understand. Both of these points are open to debate, but it is the first that concerns us here.

To investigate the optimal means of providing information, two models of the practical aspects of giving information can be applied. The basic premise of the simple deficit model is that lack of information plays a causative role in producing behaviour detrimental to health; providing relevant information, and so eliminating the deficit, would also eliminate (at least partially) the undesirable behaviour and consequent health risk. Such a deficit model can be applied to the EE concept and data: Vaughn & Leff (1981) found that relatives who were rated as high-EE tended to view the bizarre and difficult behaviour of the patient as being deliberate or at least controllable; in contrast, low-EE relatives believed that this behaviour was due to a legitimate illness which the patient was not able to control. Hence the prevalence of criticism and hostility found in high-EE relatives could be explained by the attribution of personal control and causation to the patients themselves rather than to the illness, but high ratings of emotional over-involvement found in some high-EE relatives are less easily explained by this model. The deficit model would predict that providing adequate information about schizophrenia and its consequences would alter the attributions about the causality of the patient's behaviour which are made by the high-EE relative, and thus result in a

reduction in criticism and hostility. Hence, Berkowitz *et al.* (1984) commented: "the reasoning was that if high-EE relatives could learn more about schizophrenia, they might begin to understand that some of the patient's bizarre or difficult behaviour could be attributed to the schizophrenic condition. Such understanding could be one of the apparently important changes necessary for the change from high to low EE". These authors consider information to be only one aspect of the necessary process for change, but it is an important goal of their intervention, which aims to change relatives from high to low-EE status, and hence reduce the patient's risk of relapse. Similarly, McGill *et al.* (1983) hypothesised that "family members can effectively enhance their knowledge of this illness by participating in a brief educational intervention . . . and that such knowledge results in better understanding and care from the person with schizophrenia". They believed that high levels of EE can be due to lack of knowledge about the illness, and that this may sometimes be due to an unwillingness of mental health professionals to educate relatives.

A second, more complex model—interaction—can also be applied to giving information; it draws on concepts used by medical sociologists and anthropologists to discriminate between the objective and subjective aspects of disease. The distinction between 'disease' and 'illness' has often been made; both are conceptual models to explain certain phenomena. The former, a paradigm of medicine, refers to an 'objective' pathology in structure or function of body organs or systems (Eisenberg, 1977). 'Illness' refers to the subjective effects on the patient having the disease; it is therefore the patient's perception of the disease and its consequences, and will be influenced by individual, environmental, social, and cultural variables. Helman (1981) points out that each patient has his own lay model of sickness, and that "such models, even if based on scientifically false premises, can have an internal logic and coherence and should be taken seriously by the clinician as they are the patient's way of trying to make sense of, and deal with, their ill-health in terms of their own reality". It would seem that the consumer may develop a cognitive set which influences his behaviour and the assimilation of new information.

The interaction model therefore postulates that during exchange of information, the health care professional may assume a disease model of the pathology, whereas the patient will assume an individualised illness model. Information given to the patient will be assimilated, organised, and possibly rejected on the basis of the illness model held by the patient, and not on that of the disease model, even if the patient adopts pseudo-scientific terminology. The use of lay models of sickness by the patient and his relatives is more likely in psychiatric illness, where symptoms are often manifest as changes in behaviour (verbal and overt), as opposed to physical signs of pathology.

The adoption of either a deficit or interaction model will affect the way information is communicated, as well as the goals of such provision, and probably the satisfaction and compliance of the recipient.

Applying the models to the studies

Although a number of recent studies concerning relatives

and schizophrenia incorporated an educational and informational component in their intervention, there are few published reports on the effectiveness of the education itself. However, it would seem pertinent for future work to fit what data are available to these two models.

Several studies (Berkowitz *et al*, 1984; McGill *et al*, 1983; Smith, 1984) have demonstrated that relatives receiving educational packages or components about schizophrenia do acquire information; how much is acquired, relative to the amount of information given, is of interest to the deficit/interaction debate. Berkowitz *et al*, (1984) report that their criteria for acquisition had to be set at a very low level, and that "the absence of any knowledge of aetiology is quite striking, and the tendency to retain their own version of causes of the illness is consistent across all groups". This calls into question the appropriateness of the deficit model, and suggests that it is unable to account for all the data. Further support comes from Falloon *et al*, (1981), in an early study looking at behavioural family therapy with three young men at high risk of relapse and their families. After 25 family sessions, of which the initial ten were education seminars, one mother "had not understood the rationale for continued maintenance medication and was encouraging her son to take a proprietary tonic instead". The interaction model would predict that some relatives might be very resistant to changing their existing lay conceptualisation of the illness.

Are relatives critical, hostile, or over-involved due to a lack of information, as the deficit model suggests? The fact that Berkowitz *et al* found little difference between information known about schizophrenia at baseline between relatives who were rated high- or low-EE does not support this hypothesis. Does information eliminate 'undesirable' behaviour? In the case of high-EE relatives, this would involve the study of whether those relatives who acquired information about the illness and its management consequently changed their behaviour in relation to the patient. If this were so, how much did the information-giving contribute to the success of reducing relapse rates in the psychosocial intervention? If a direct relationship could be demonstrated between acquisition of information, relative's behaviour, and the patient's symptomatology or relapse, there would be strong support for a deficit model. However, the relatives' resistance to changing their views suggests that the relationships between the variables is more complex, an investigation of these relationships would require an analysis of a wider range of variables than information acquisition *per se*.

In Smith's (1984) study, attention was paid to a wider number of variables. Patients who were living with their families in the community were randomly allocated to one of two groups; families in one group met on four weekly occasions with others, and were provided with information about schizophrenia through verbal presentation, discussion, written handouts, and video. A second group received information in the form of written material through the post. Both groups had to complete homework exercises. Besides attempting to assess the acquisition of information, Smith also attempted to look at the consequences of giving information on various patient and relative variables. Like Berkowitz *et al* (1984) and McGill *et al* (1983), she found

that both groups significantly increased their knowledge concerning schizophrenia, and both showed a decrease in measures of fear and worry. Relatives in both groups demonstrated a decrease in scores of the symptom rating test (Kellner & Sheffield, 1973) after education, but no change in perceived burden of the patient, and there were no changes in patients' symptomatology or disturbance. Interestingly, and contrary to a deficit model, education did not result in a reduction in criticism (although this measure is not the same as critical comments assessed in EE), and the reduction in fear and symptom levels in relatives was independent of information acquired about schizophrenia. Thus, although the provision of information may result in benefits to the relatives, even when provided with such minimal professional contact as can be given through the post, it does not appear that this benefit results directly from information acquisition. However, the method of recruitment of this sample of patients was different from other studies, so they may not be an equivalent population.

Implications

It has been demonstrated that the simple deficit model cannot account for the available data in the studies reported, and that the interaction model might be more profitably adopted. This will affect the way in which information is communicated: most obviously, there will be a need to tailor the information to the individual family case, rather than focusing on psychopathology in general. Even more so than in general medicine, there will be the need to simplify and reduce the amount of information presented.

The goals of the informational input will also need to be examined. The acquisition of information may have little impact on the individualised illness model that the relative holds, and consequently little effect on their behaviour. Evaluation of the amount of information recalled may not be the most important variable: much closer attention will need to be paid to the illness models of relatives, behaviour of information recipients (family members in this case) in relation to the patient, and patient outcome variables.

Assessing the outcomes of information-giving

The behavioural literature of staff training is useful in looking at the effects of education, because there are similarities in using families as rehabilitative agents and in teaching behavioural techniques to front line staff working with client groups who have severe chronic problems. Ziarnik & Bernstein (1982) have outlined five different outcome measures which have been used to evaluate staff training: subjective (what trainees report); cognitive (what knowledge is gained); behavioural (how training is applied); client-centred (the effects on the client); and organisational (the effects on the organisation). A cautionary parallel is that although staff training often implicitly adopts a deficit model, there is little unequivocal evidence that such training procedures produce stable changes in staff behaviour (Ziarnik & Bernstein, 1982; Woods & Cullen, 1983). Most evaluations of staff training have only examined the first two

outcomes (subjective and cognitive), and these measures may have little effect on the more meaningful outcomes of behaviour change in staff and any resultant client improvement or progress. This classification might usefully be applied to outcome measures evaluating the effect of giving relatives information about schizophrenia.

Subjective. i.e. relatives' reported feelings about the provision of information. Measures could include self-reports of satisfaction about the content, form, or presentation of material, as well as measures of any non-specific effects that relatives attributed to the service, such as reassurance or support; the latter might include measures of mood or anxiety.

Cognitive: i.e. measures of knowledge of information about schizophrenia acquired by relatives as a result of the information-giving exercise. Measures would include the amount of technical or academic information gained, e.g. the symptomatology and causes of schizophrenia. According to the interaction theory, more important measures would include those tapping the individualised illness model of the relatives: their attitudes, beliefs, and attributions about the cause and consequences of the illness as it affects their family member

Behavioural: i.e. any changes in the behaviour of the individual family members in relation to the patient as a result of the information received. The aspects of behaviour to be measured would be determined by the theoretical orientation of the researchers or practitioners, although the relationship between information, acquisition, and compliance with treatments may be of general interest. The latter might include measures of relatives' participation in medication and therapy compliance. Those seeking to reduce EE might attempt to measure aspects of behaviour directly related to its concept, such as behaviour related to criticism or hostility (arguments, punishments) or to emotional over-involvement (intrusiveness, self-sacrifice, dependency-maintaining behaviour). Conversely, increases in positive behaviour such as strategies to avoid criticism (reduction in contact time, problem-solving discussions) or independence-encouraging behaviour (prompting of self-care and independent social behaviour) should also be measured, to avoid concentrating exclusively on negative aspects of the situation. Direct observational measures of such behaviour in 'real' life would be full of practical and methodological problems. Reliance on the reported behaviour of the relatives might be necessary, increasing the reliability of self-reports with those from other observers (possibly the patient or other family members). Alternatively, behaviour observed and measured in more artificial laboratory conditions and correlated with EE measures might be used (Kuipers *et al.*, 1983).

Client-centred i.e. the measurement of patient variables, including the frequency of relapse and hospital admission, along with reduction in symptomatology and the real and

perceived reduction in 'problem' behaviours. More positive measures might also be included, such as increases in independent functioning.

Organisational. In the case of more than one relative or significant household member, this might refer to changes in significant family interaction variables. As with measures of relatives' behaviour, what was identified as 'significant' would be determined by both the theoretical and empirical findings. The use of applied behavioural analysis as an assessment tool might be useful in identifying functional relationships between family members' behaviour which resulted in outcomes detrimental to the patient (see Goldiamond (1974) and Owens & Ashcroft (1982) for a discussion of functional analysis). Alternatively, interaction between family members which were correlated with patient prognosis or EE might be used (e.g. problem-solving, Falloon *et al.*, 1982).

The use of the multiple outcomes framework in association with the interaction model may be helpful in evaluating attempts to give relatives information; for example, the acquisition of purely academic knowledge about schizophrenia in general may have little relationship to any of the other outcome measures. Several reasons could account for this. A relative might acquire all the facts presented, but reject the idea that they appertain to his family member; or a relative might believe that the patient has some other condition (in our experience including depression, drug addiction, or no problems at all). Alternatively, the academic knowledge presented or acquired may have no relevance to desired change in behaviour or consequent progress of the patient. In the cases of both rejection and irrelevance, positive changes in the relative's behaviour or in client-centred or family variables would not be expected, but with irrelevance subjective gains from the non-specific effects of service contact might be found. In the case of rejection some relatives might express dissatisfaction, since the disease model presented was at odds with the illness model (or non-illness model) held.

Attitudes, beliefs, and attributions about the illness may bear more relationship to relatives' behaviour than may academic or technical knowledge. The evidence from the EE studies would support this hypothesis: for instance, a relative may be unaware of the name of the disease or its diagnostic symptoms, but may believe that the patient has a legitimate illness, and attribute whatever the person does when ill to reasons beyond their control, and consequently may act in a supportive manner. Conversely, a relative may believe that the patient hears voices, but think that this phenomenon is within the person's control; although 'knowing' one symptom of the disease model, this may not influence the relative's consequent behaviour. Alternatively, understanding that the patient is suffering from an illness may contribute to higher levels of over-involvement, for example over-protective or self-sacrificing behaviour.

Guidelines

The study of how best to present information to relatives about schizophrenia has a relatively short

history, but the interaction model and the use of multiple outcome variables may provide fruitful areas for future work. Meanwhile, on the basis of existing studies and the theoretical discussion presented here, the following guidelines are suggested for practitioners wishing to embark on giving information to relatives.

1. There is a need to assess and take into account both patients' and relatives' perceptions of the illness, prior to embarking on the task of giving information. If we adopt the interaction model, then we must take the view that the information is not given in a vacuum. This will involve probing patients and relatives about their ideas as to the cause and consequences of the illness, as well as their views on the current treatments received and opinions as to how its consequences are best managed in the home environment.

2. There is a need to accept the individualised illness model, which involves taking the views of patients and relatives seriously, while presenting alternative explanations and ways of coping. It will also involve presenting information about the particular patient's symptomatology, rather than focusing too broadly on psychopathology in general.

3. There is a need to be selective about the information which is to be conveyed. Since previous studies of doctor-patient communication showed that only a small number of items of information are remembered by patients, we should concentrate on those which are hypothesised to be most useful in assisting patients and relatives to cope with the problems caused by the illness and to comply with medical treatments. Providing simple, easy-to-read written information about these facts may facilitate learning.

4. Given that we are dealing with individualised illness models, shaped by many complex personal, environmental, and social variables, it should not be

assumed that everyone will assimilate the information at the same rate. Consequently, perceptions of the illness must be reassessed routinely, following the exchange of information. In this way, patients and relatives whose views about the illness are most resistant to change and whose consequent behaviour may be most potentially detrimental to the patient might be identified, and offered further help, information, and alternative coping strategies.

5. The interaction model would predict that the longer the duration of the illness, the more time and opportunity there has been for a personalised lay view of that illness to have become established. This will particularly be the case where no 'professional' view has been offered as an alternative. Consequently, the sooner information is given after the illness begins, the more likely are professionals to influence individualised illness models.

6. The consistent results of the measure of EE in research on relapse rates has often led to requests for some type of clinical application of this measure. However, because of the practical problems of using this lengthy interview and rating method, it may be more appropriate to look for a clinical methodology based around an assessment of the relative's knowledge of schizophrenia, using broad outcome variables. By eliciting the relative's attitudes, beliefs, and attributions concerning the illness and their consequent behaviours in interactions with the patients, an assessment of the relatives' existing coping strategies could be made. Development of this type of approach might be an appropriate and clinically useful application of the concept of expressed emotion.

Acknowledgements

We would like to thank Max Birchwood, Ian Falloon, Hugh Freeman, Christine Vaughn, Jo Smith, and Susan Watts for discussion about these topics.

Delineating Social Phobia

L. SOLYOM, B. LEDWIDGE and C. SOLYOM

The natural history—including psychiatric symptoms, precipitating factors, onset and course of illness, and personality characteristics—of 47 social phobics, 80 agoraphobics, and 72 simple phobics was examined. The social phobia group differed from the agoraphobia group by having a lower mean age, fewer females and married members, and a higher educational and occupational status. They were less fearful generally, less obsessive, and less likely to follow a fluctuating or phasic course. There was overlap between the two groups with regard to main phobias, and they were similar with regard to adjacent symptomatology. Both the social and agoraphobia groups differed in similar and significant ways from simple phobics.

DSM-III (American Psychiatric Association, 1980) lists three criteria for the diagnosis of social phobia:

- (a) a persistent, irrational fear of, and compelling desire to avoid, a situation in which the individual is exposed to possible scrutiny by others, and fears that he or she may act in a way that will be humiliating or embarrassing
- (b) significant distress because of the disturbance and recognition by the individual that his or her fear is excessive or unreasonable
- (c) not due to another mental disorder, such as major depression or avoidant personality disorder.

In both DSM-III and ICD-9 (Commission on Professional and Hospital Activities, 1978), social phobia and agoraphobia (with and without panic attacks) are the only two phobic conditions accorded diagnostic categories separate from the general diagnosis of simple phobia. Before the third revision, the DSM included only one phobic disorder: phobic neurosis.

Theoretically one can develop a phobia to any object or situation (Mowrer, 1947), but the observed range of phobic objects is distinctly limited. The practice, until recently, of classifying each phobia on the basis of the feared situation and cataloguing each by adding the suffix *-phobia* to a Latin or Greek word denoting the thing feared, prevented the recognition that certain fears cluster together. However, if it can be shown that a certain cluster of phobias systematically and consistently differs from others in terms of aetiology, other symptomatology, age of onset, course and response to treatment, then a separate diagnostic category can be justified. Such is the case with the DSM-III sub-category of agoraphobia.

That agoraphobia differs fundamentally from other phobias is well documented. Most agoraphobic patients are women, and may also suffer from other phobias, have spontaneous panic attacks, depression, depersonalisation and mild obsessions. Snaith (1968) compared 27 agoraphobic patients with 21 patients suffering from either social or specific miscellaneous phobias: those suffering from agoraphobia were more anxious, their illness more often ran a remitting course, and their distribution of phobias was markedly different from the patients with discrete phobias. Factor analyses of the self-report data of phobic patients have consistently yielded a distinct factor of agoraphobia (Marks, 1967; Hallam & Hafner, 1978; Arrindell, 1980).

The evidence for a category of social phobia separate from both agoraphobia (with mild social phobias as part of the syndrome) and other simple phobias is less substantial. Marks (1969) assigned a separate category to social phobia 11 years before DSM-III, but the data he describes to define the category fail to distinguish social phobia from agoraphobia. Drawing on the results of six published and two unpublished studies (Gelder *et al*, 1967; Kelly, 1966; Lader, 1966; Lader & Wing, 1967; Marks & Gelder, 1966; Martin *et al*, 1969), Marks compared agoraphobics, social phobics, animal phobics, miscellaneous specific phobics, and illness phobics on 11 variables (percentage of women, onset age, treatment age, overt anxiety, modified Cornell Index, neuroticism, extroversion, galvanic skin response (GSR) spontaneous fluctuations, GSR habituation rate, resting forearm blood flow, and eye-blink conditioned response acquisition). The social phobics differed significantly from the animal phobics on six of these variables (onset age, overt anxiety,

modified Cornell Index, neuroticism, GSR spontaneous fluctuations, and GSR habituation rate), but did not differ significantly from the agoraphobics on any of the variables. Marks (1969) concluded cautiously: "We need to know more about social phobics before definitely classifying them on their own". Amies *et al* (1983), on the other hand, compared a group of social phobic patients with a group of agoraphobics on demographic, clinical, and questionnaire data, and concluded that significant differences on important variables (age, sex, social class, age of onset, main phobic complaint, and type of autonomic response) justified the recognition of two distinct syndromes. They conceded, however, that 50% of the agoraphobic patients experienced anxiety in social situations and that 25% of social phobics experienced anxiety in agoraphobic situations, in both cases at significantly lower intensities; the two groups did not differ with respect to their symptoms (e.g. anxiety, depression, obsessional symptoms).

Method

The 199 patients in the present study were consecutive referrals, primarily from other psychiatrists, over a 16-year period (1965–1980) for behavioural treatment of phobia. Following the establishment of our behaviour therapy unit in 1965, patients who had not responded to other treatment were referred to the senior author. Diagnosis was confirmed or clarified during a semi-structured clinical interview. 80 patients were diagnosed as agoraphobic, defined as 'fear of leaving home, of being alone at home or on the street, in crowds, of travelling by car, bus or train' (Solyom *et al*, 1972); 47 were diagnosed as suffering from social phobia, defined as a fear of performing (e.g. speaking, writing, eating, using a public washroom) in the presence of others. By emphasising fear of performing, we distinguish social phobia from fear of crowds, where the patient is anonymous—a classic symptom of agoraphobia. Social phobics may have avoided social situation for fear of blushing, speaking, trembling, or panic attacks. However, the 72 simple phobics suffered from a single but life-disrupting fear—animals, heights, etc. (e.g. an estate agent, afraid of dogs, could not function adequately at work; a snake phobic could not watch TV for fear a snake might unexpectedly appear on the screen), and did not fall into the agoraphobia or social phobia categories. The most common simple phobias treated were fear of dogs or cats ($n=10$), cancer and other diseases ($n=9$), airplanes ($n=6$), snakes ($n=5$), and bees or spiders ($n=5$). Patients whose avoidance was secondary to some other major disorder (e.g. social phobia due to paranoid fear or withdrawal, resulting from clinically significant depression) were not included in the sample. Despite being assessed during a 15-year period prior to its publication, these diagnostic criteria are identical to those of DSM-III.

After the diagnosis had been made, the following data were collected before treatment was administered.

Psychiatric Questionnaire (Solyom *et al*, 1971). This was administered in the form of a semi-structured interview by the senior author, and in some cases by a second psychiatrist as well. It included description and ratings of the phobic and obsessive symptoms, depression and other clinical features, course of disorder, and personal history. Symptoms were rated on a five-point scale (0–4), with a rating of 0 indicating no symptoms and 4 indicating incapacity. Only ratings of 2 (indicating definite uneasiness and frequent avoidance) or more were considered clinically meaningful.

Self-rating of symptoms. The patient was asked to rate his symptoms on a scale of 0–4 by choosing one of the five statements that best described how he had been feeling with respect to each symptom during the previous week. The five points roughly corresponded to absent, mild, moderate, severe, and extremely severe. Symptoms rated by the patient were his main phobia (his worst fear), two measures of anxiety (cognitive apprehensiveness and somatic symptoms of anxiety), depression, depersonalisation, obsessive symptoms, and change of habits.

Self-rating of social maladjustment. The patient was asked to rate on a similar five-point scale the extent to which his symptoms interfered with adjustment at work (either outside the home or as a housewife), adjustment with regard to leisure activities, sexual adjustment, social adjustment within and outside the immediate family, and expressed self-satisfaction.

The three rating scales listed above were adapted from Gelder & Marks (1966), who measured inter-rater reliability as well as the reliability of the psychiatrists' ratings compared with the patient's own ratings of the same symptoms.

IPAT Anxiety Scale Questionnaire (Cattell & Scheier, 1963). The patient completed the IPAT. Half of its 40 questions refer to overt, symptomatic, conscious anxiety; the remainder consist of covert, hidden-purpose probes.

Fear Survey Schedule (Wolpe & Lang, 1964). This is a patient self-rating, on a five-point scale (from 'not at all' to 'very much') of the amount of fear elicited by 72 common phobic stimuli. These stimuli fall into six clusters of fears: death and tissue damage (18 items); social (17 items); other, e.g. large open spaces, crossing streets, journeys by train, bus, car (16 items); animals (9 items); miscellaneous (8 items); and noise (4 items).

Maudsley Personality Inventory (MPI) (Eysenck, 1958). Eysenck's 48-question inventory yields scores on two orthogonal dimensions of personality: neuroticism or emotionality, and extroversion.

Leyton Obsessive Inventory (LOI). (Cooper, 1970). This consists of 69 items, 46 of which relate to symptoms

of obsessive—compulsive neurosis and 23 to obsessive personality traits. In addition, the LOI has two intensity scales—resistance and interference—which measure the degree to which the patient resists his or her obsessive symptoms, and the extent to which the symptoms interfere with other activities. Because the questionnaire was published five years after our data collection began, scores are available on only 24 patients.

General Information Sheet. This single-page questionnaire elicited demographic information about the patient, his parents and siblings.

The three groups of social, agoraphobic and simple phobics were compared with respect to symptomatology and other aspects of natural history and demographic and personality variables. On those variables that were ordinal or better with respect to level of measurement, the statistical analyses consisted of analyses of variance followed, when the overall difference among the three groups was significant at the one in twenty level, by *t*-test comparisons of the groups two at a time, using the Tukey B procedure (Wine, 1964) to test for differences. On nominal variables, the groups were compared using the chi-squared method. Missing data were not estimated; analyses of variance, *t*-tests and chi-squares were computed using available data only.

Results

Social phobics were found to differ from both agoraphobics, as Amies *et al* (1983) reported, and from simple phobics, as Marks (1969) demonstrated.

Demographic data

Demographic data for all groups are given in Table I. Compared with the agoraphobia group, the social phobia group was younger, had fewer women and married persons, was better educated and had more members in the professions. Compared with the simple phobics, the social phobics were younger and fewer were female or married, but they did not differ significantly with respect to education or occupation.

Symptomatology

The three groups differed in the content of their phobias, but not in the intensity of their main phobia (worst single fear, as described by the patient; for a social phobic this might for example be 'parties'; for an agoraphobic it might be 'supermarkets'). Among the three groups, the agoraphobic patients scored significantly higher on ratings of agoraphobia, the social phobics on social phobia, and the simple phobics on simple phobia (full details of results are obtainable from the authors on request).

On the total FSS score—a measure of general fearfulness—the agoraphobics obtained a score of 133, which was significantly higher than the 99 and 91 returned by the social phobics and simple phobics respectively.

The social fears score on the FSS was identical in the agoraphobia and social phobia groups. In addition, 55% of the agoraphobic patients suffered from clinically significant social phobias (≥ 2 on a 0–4 scale) as rated by a psychiatrist, and 30% of the social phobics suffered from clinically significant agoraphobic symptoms.

On measures of associated symptomatology, the social phobics and agoraphobics did not differ on the four measures of anxiety, on the two measures of depression, or on the self-rating of maladjustment. On each of these measures, the social phobics and agoraphobics had significantly higher scores than the simple phobics, with the exception of self-rated depression. The agoraphobics were rated higher on rituals, ruminations, and horrific temptations than the social and simple phobics, but the three groups did not differ on self-rated scores of rituals, pervasive doubts, and horrific temptations.

The mean symptom scores for all three groups on the LOI (social phobia, 18.6; agoraphobia, 19.1; simple phobia, 13.2) fell between the norm for obsessive patients (33) and the norm for normal men (9) and normal women (11) (Cooper, 1970). The three groups did not differ significantly on this measure.

History of illness

Data on the history of illness for all three groups are presented in Table II. The social phobics experienced their first phobic symptom significantly earlier than the agoraphobics, but significantly later than the simple

TABLE I

phobics. With respect to age of onset of the illness (i.e. when the symptoms for which the patient ultimately sought help became continuous), the social phobics and the agoraphobics did not differ significantly; both occurred significantly later than the simple phobics.

The Psychiatric Questionnaire listed 14 life events occurring during the six months preceding the onset of the present illness: fright, acute danger, serious illness, death of a relative or friend, domestic crisis, unavoidable conflict, sexual problem, bethrothal, occupational problem, school problem, childbirth, pregnancy, menopause, and other crises. A larger proportion of the social and agoraphobic groups, compared with the simple phobia group, cited one or more of the precipitating factors. The three groups differed significantly with respect to four precipitants: domestic crises, occupational or school difficulties, and fright. Compared with the agoraphobics, the social phobics more often cited occupational (7% vs 0%) or school (10% vs 0%) difficulties and less often domestic crises (19% vs 33%). Compared with the simple phobics, the social phobics more often cited occupational (7% vs 0%) or school (10% vs 2%) difficulties and less often mentioned fright (12% vs 23%). Fright among the simple phobics usually involved the phobic object (e.g. being stung by a bee).

The patients were categorised according to Ingram's (1961) four types of course of disorder (with the additional category of 'getting better', which characterised one of our patients). The modal course for agoraphobics was 'fluctuating and phasic' (63.3%). For social phobics the figure was 46.1%, and for simple phobics, 39.9%; these differences did not reach statistical significance.

Delay in seeking help was defined as the interim between the time the phobic symptomatology became continuous and when the patient first sought psychiatric help.

There were no differences among the three groups in the incidence of neurosis, personality disorder, psychosis, and organic brain syndrome among fathers, mothers, siblings, or other relatives regardless of the relative group examined.

Personality traits

The obsessional personality trait scores from the LOI of the social phobics (9.9) and the agoraphobics (10.5) were much higher than those of the simple phobics (6.2), but the overall difference among the three groups did not reach statistical significance ($F = 2.6$).

On the MPI, the neuroticism scores of the social phobics (29.4) and the agoraphobics (30.2) did not differ from each other, but both were significantly higher than the scores of the simple phobics (21.4), who scored in the same range as normals: 20.9 and 19.9 for American and English students respectively (Eysenck, 1958). A similar pattern emerged with respect to extroversion, with the social phobics (19.2) and the agoraphobics (20.6) differing significantly from the simple phobics (25.3), whose mean extroversion score was closer to the normal score: 28.5 and 24.9 for American and English students.

Discussion

The results of the present study support the recognition of social phobia as a distinct diagnostic category. Although sharing features with both agoraphobics and simple phobics, the social phobics do not fit satisfactorily into either category.

Our comparison of social phobics with agoraphobics confirmed many of the differences reported by Amies *et al* (1983), but produced a few

discrepancies. Like them, we found more males, more single persons, better education, and higher occupational status among the social phobics. Like the British samples, our socially phobic patients were as anxious and depressed as were the agoraphobics, and had equally high neuroticism scores. We also found, like Amies *et al*, that the first symptoms appeared earlier in life in the social phobics than in the agoraphobics. Discrepancies between the two studies involve obsessive-compulsive symptoms, delay in seeking help, and extroversion scores: whereas Amies *et al* reported no differences between the two groups on obsessional symptoms (undifferentiated), we found higher ratings for rituals, ruminations, and horrific temptations among the agoraphobics. As was the case in Britain, however, few patients in either group had clinically significant obsessive symptoms (Amies *et al* reported obsessive symptoms in 20% of each group). Our data on delay in seeking help (social phobia 3.7 years, agoraphobia 1.0 year) are apparently substantially different from those of Amies *et al* (social 12 years, agoraphobia 10 years), but if delay is calculated from the time of first symptom, as was done in that study, rather than from the time when the illness became continuous, the delay for social phobics is increased to 11.2 years, which is closer to Amies' figure of 12 years. The revised definition of delay for the agoraphobia group, however, yields a figure of 2.5 years, which is much shorter than the 10 years that Amies reports. One possible explanation is that agoraphobic subjects came to therapy following considerable publicity about the diagnosis and its favourable response to behaviour therapy. Shortly thereafter, the Medicare system was introduced in the USA, enabling patients to come for treatment without direct cost.

We found no differences between the social phobics and agoraphobics on either of Eysenck's orthogonal dimensions of personality, whereas the social phobics of Amies *et al* scored lower than their agoraphobic patients. This discrepancy may in part be accounted for by the fact that we used the MPI and Amies used the later version—the Eysenck Personality Inventory (Eysenck & Eysenck, 1964), which may support different spectra of the two dimensions.

The overlap between social phobia and agoraphobia, first reported by Amies *et al* (1983), also occurred in our groups. Among the social phobics, 30% had clinically significant agoraphobia (though rated at lower intensity than their social phobia), among the agoraphobics, 55% had clinically significant social phobia (again, rated at lower intensity than their agoraphobia). Thus, one can conceive of

three groups—social phobia, agoraphobia, and a group with combined social and agoraphobia. The diagnosis was based, however, on the presenting complaint (the 'main phobia') of the patient. Had we assessed 'pure' social phobics and 'pure' agoraphobics, the differences between them may have been enhanced, most notably perhaps in terms of situations avoided and types of autonomic and cognitive responses. For instance, a social phobic woman also avoided supermarkets; the stated basis of her fear: 'What if I meet someone I know?'. Many agoraphobics, if not all of them, are also fearful of making fools of themselves because of their phobic responses.

The problem of overlap may also arise because both agoraphobia and social phobia may be based on fear of having a panic attack; i.e. both may suffer from panic disorder (DSM-III).

We have attempted to summarise the differences between social phobics and agoraphobics in Table III. The separations are derived by definition and from clinical observations, and would perhaps be supported by research findings on 'pure' social phobics and agoraphobics.

The data presented here support the view (Snaith, 1968; Solyom *et al*, 1974; Klein, 1981) that agoraphobia and also perhaps social phobia are produced by essentially different mechanisms from those which seem to produce simple phobia. The typically tangible onset (fright involving the phobic object is the most common precipitant), and their modal 'constant static' course are consistent with the view that simple phobias are conditioned classically and maintained instrumentally by avoidance (Mowrer, 1947). Mowrer's two-factor theory, however, should be amended to account for the non-random variation in the content of phobias by including the notion that humans are more 'prepared' to develop certain conditioned fears because of their importance to the survival of the species (Seligman, 1971; Seligman & Hager, 1972).

The significantly higher level of anxiety among the agoraphobics and social phobics, the less discrete nature of the phobic object, and the lack of correspondence in content between precipitating factors and avoidance of these phobic situations and adjacent symptomatology are inconsistent with the conditioning theory of aetiology.

How then might they develop? One possibility is that separation anxiety (agoraphobia) and fear of strangers (social phobia)—common fears in childhood that usually disappear by the age of four (Jersild & Holmes, 1935)—may be incompletely unlearned, so that later, when the person's general anxiety reaches a critical level because of calamitous

TABLE III
Differences in features of man phobia, as described by social phobics and by agoraphobics

Feature	Social phobics	Agoraphobics
Situations avoided	Parties and social gatherings Meeting friends or acquaintances	Crowds in public places Public transport Being alone
Response	Blushing Tremor Stammering	Panic—dyspnea, tachycardia, faintness, etc.
Activity avoided	Speaking, eating, writing in public	Travel, shopping
Anticipatory thoughts	What if I stutter, blush?	What if I faint, die, lose control
Fear expressed	Embarrassment Loss of control	Panic, loss of control Embarrassment
Constancy of response	Constant	Fluctuates
Modifiers of response	A spouse (for some)	Presence of dependable other
Course	More frequently static (44%)	More frequently fluctuating and phasic (63%)

events, a domestic crisis, or difficulties at work or school, the fears re-emerge. The failure to unlearn may result both from maternal over-protection and modelling of maternal fear behaviour. There is evidence that mothers of agoraphobics are more anxious and more over-protective than mothers of normal subjects (Solyom, *et al*, 1976), and that both parents are perceived as less caring and more over-protective by social phobics (Parker, 1979). Whether maternal over-protection elicits fear behaviour in the child or the fearful child evokes over-protective behaviour in the mother, the general effect of over-

protection seems to be the preservation of separation anxiety or attachment behaviour (Bowlby, 1969) and fear of strangers (Freedman, 1965; Schaefer, 1966)—the basis of 'preparedness' for agoraphobia or social phobia.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine¹, trifluoperazine² and haloperidol³, but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia⁴

sulpiride
DolmatilTM
IN SCHIZOPHRENIA

Prescribing Information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 100mg sulpiride. **Indications:** Acute and chronic schizophrenia. **Dosage:** A starting dose of 400mg to 800mg daily given as one or two tablets twice daily (morning and early evening) is recommended. **Predominantly positive symptoms:** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily. **Predominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily. **Mixed positive and negative symptoms:** 100mg-600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment. Clinical experience in children under 14 years of age is insufficient to permit specific recommendations. **Contraindications:** Phaeochromocytoma. **Warnings:** Extrapyramidal reactions principally akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary. After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dosage in a small number of patients. In aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms. Care should be exercised where hypomania is present. Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions:** Epilepsy - anti-convulsant therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney. **Pregnancy:** the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number:** PL 5299/0006. **Legal category:** POM. **Basic NHS cost:** 35p per day at dose of 600mg daily. **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. **Trade Marks of E R Squibb & Sons Ltd (Distributor):** DOLMATIL - Trade Mark of SESIF. **Authorised User:** Delagrangue Ltd. **References:** 1. A SCHIZOPHRENIC.

Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.

A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*
haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼ **Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. **Use in Pregnancy:** The safety of haloperidol in human pregnancy has not been established. **Precautions:** Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. **Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. Side Effects:** In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. **Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50–100mg every 4 weeks, in moderate symptomatology 100–200mg every 4 weeks; in severe symptomatology 200–300mg or more every 4 weeks. **Product Licence No. PL0242/0095, PL0242/0094. Basic NHS Cost: 100mg/ml: 1ml x 5 £24.00, 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from Janssen Pharmaceutical Limited, Grove, Warrage, Oxon OX12 0DQ.**

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.¹

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,^{2,3} and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil

DEPOT PHENOTHIAZINE PALMITATE

Piportil Depot Prescribing Information

Dosage: (Adults) Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension,

hyperhidrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08½ ampoules (PL0012/0117). **References:** 1. The Use of Seclusion in Psychiatric Hospitals in the Newcastle Area

P. THOMPSON

Between 1981 and 1984, the frequency with which seclusion was used decreased in Newcastle. Secluded patients were younger, more often male, unmarried, unemployed, and admitted formally, and there was an association with certain diagnoses. Most seclusions occurred early in the hospital stay, mainly in the daytime, especially at mealtimes, and first seclusions were the longest. Violent incidents were usually associated with non-psychotic patients, and staff were the commonest victims. Medication used was major tranquillisers or paraldehyde.

Although seclusion has been in use for many centuries, early asylums used mechanical restraint to control disturbed patients. By the early nineteenth century the emergence of 'moral treatment' for the mentally ill, developed by Pinel, Conolly, Hill and others, led to the use of seclusion in preference to mechanical restraint.

With the development of new drugs, in particular chloral hydrate and bromides, workers such as Hill, Charlesworth, and Smith felt that seclusion "as a means of control, might be as successfully and usefully dispensed with as instrumental restraint had already been" (Walk, 1970). The availability of paraldehyde and barbiturates led to further changes in the management of the mentally ill in the early 1900s, and thereafter ECT and other modern treatments made their impact.

By the 1950s seclusion seemed largely restricted to the 'disturbed wards', many workers believing that it promoted neglect and abuse, besides provoking fear and resentment in the patient. The 'open-door' movement, encouraged by the Mental Health Act of 1959, led to staff in psychiatric units becoming less experienced in coping with violence, less willing to accept it, and happy to give up seclusion rooms.

Seclusion is, however, still in use, but information about its use is currently limited and comes largely from the USA, with the exception of a small study from the UK (Campbell *et al.*, 1982).

'Restraint' is the enforced control of patients' ability to behave in ways that threaten or cause harm to themselves, to others or to property. It may be manual, mechanical, situational, or chemical. 'Situational restraint' includes the use of special hospitals, secure units, locked wards and seclusion.

Thus 'seclusion' is a form of situational restraint where the patient is forcibly isolated from other patients in a room, the door of which is locked from the outside. It is used most often following manual

restraint, makes mechanical restraint unnecessary, and allows chemical restraint to come into effect (Wells, 1972). It may be that the environment of the seclusion room itself has a calming effect, but there are essential differences between seclusion and the behavioural technique of 'time-out': a reinforcing stimulus need not be identified for seclusion, which is always an emergency procedure, whereas 'time-out' is a planned conditioning method not necessarily involving the use of a locked room.

Method

The study looked retrospectively at the use of seclusion from 1981 to 1984 in all the psychiatric units of the Newcastle area, serving an initial population of 426 000. It did not cover admissions or seclusions in units for mental subnormality, psychogeriatrics and child psychiatry. Seclusion does not occur in the latter two, and it is rarely used in long-stay wards.

For the year 1981, all general adult psychiatric admissions were studied in more detail, to obtain appropriate control groups. Information was obtained from case-notes, admission documents, nursing notes, and seclusion records. Statistical tests used were Student's *t* test, chi-squared analysis with Yates' correction factor, Fisher's exact test, and the Wilcoxon rank-sum test.

Results

Over the period studied, there was a decline both in the number and rate of seclusions in Newcastle (Table 1). Most patients were secluded once only, and changes were most pronounced in the group of patients most frequently secluded.

Of patients admitted in 1981, 10.4% (23) with bipolar affective disorder were secluded ($P < 0.001$), 6.9% (22) with schizophrenia were secluded ($P < 0.01$), and 37.5% (3) of mentally handicapped men were secluded ($P < 0.001$). Other diagnoses were not significantly associated with seclusion. Overall, 77.3% (51) of secluded patients had diagnoses of psychotic illnesses, compared with 49.2%

TABLE I
Number and rates of seclusions in 1981-1984

	Year			
	1981	1982	1983	1984
Number of admissions	2017	1636	1867	1884
Number of patients secluded	66	56	42	49
Patients secluded/1000 admissions	33	34	23	26
Number of patients with 1 seclusion	39	35	19	31
Number of patients with 2-3 seclusions	15	12	12	11
Number of patients with 4-9 seclusions	8	6	11	1
Number of patients with >9 seclusions	4	3	0	0

TABLE II
Nature of incidents resulting in seclusion in 1981, and frequency of repetition

(991) of controls ($P < 0.001$), and 61% (41) of secluded patients were men ($P < 0.05$).

The secluded group had a mean age of 36.1 ± 13.6 years, compared with 44.4 ± 16.0 years for the controls ($P < 0.05$). Secluded patients were admitted for a median of 29 days, compared with 20 days for controls ($P < 0.01$). Only 36.4% (24) of secluded patients were married, while 52.9% (898) of controls were ($P < 0.001$), and only 17.1% (7) of secluded men were employed compared with 52.6% (430) of controls ($P < 0.001$).

While previous admission was unrelated to seclusion, compulsory admission under the Mental Health Act (1959) was associated with subsequent seclusion; 51% (39) of secluded patients had been admitted formally, compared with only 8.4% (162) of all admission. Of all formal

admissions, 19.4% were later secluded, as against only 1.9% of informal admissions ($P < 0.001$).

The type of incidents resulting in seclusion are shown in Table II. Of the 12 patients who were repeatedly secluded (i.e. four or more times), eight were male and ten had psychotic illnesses. There was a median gap of two days between seclusions, and in this group of patients incidents tended to be more often acts of violence, to self or others.

First seclusions were longer (median 9.1 h) than subsequent seclusions (median 3.3 h), $P < 0.01$, and the overall duration of seclusions ranged from 10 min to 25.5 h (median 4.3 h). Most seclusions occurred shortly after admission, 25% (54) within 24 hours. Of these 'early' seclusions, 67% (36) occurred between 6 p.m. and 6 a.m. Overall, however, most of them occurred in the daytime,

57% (123) happening between 6 a.m. and 6 p.m. The three mealtime hours accounted for 54% (23) of seclusions of non-psychotic patients, but only 14% (23) of those involving psychotic patients ($P < 0.001$).

There were 12 patients who were suffering from other illnesses (e.g. cardiac failure, faecal impaction) at the time of seclusion, and 29% (19) of cases were noted to have a current alcohol or drug problem in addition to their main psychiatric diagnosis. None of the secluded females had been in prison, but 30% of psychotic and 63% of non-psychotic male patients had been.

Only ten patients were secluded without 'as required' medication. Major tranquillisers were used alone in 40% (86) of incidents, tranquillisers with paraldehyde in 19% (40), and paraldehyde alone in 8% (17). A benzodiazepine was used once (< 1%).

Discussion

The percentage of patients found to have been secluded in this study was low compared with the US figures, but diagnoses were similar - except that bipolar affective disorder was a larger and schizophrenia a smaller group in Newcastle, probably reflecting different diagnostic criteria (Phillips & Nasr, 1983; Soloff, 1983). The decrease in the use of seclusion between 1981 and 1984 may have been related to the introduction of the Mental Health Act in 1983.

The findings in relation to age and marital and employment status probably reflect the more disturbed characteristics of this group of patients, and the onset, duration, severity, and social effects of their illnesses.

Staff intolerance of threatened violence in males resulted in 36 seclusions of males, compared with only two of females ($P < 0.001$). The most frequent type of incident was violence to others, staff being the commonest victims. Non-psychotic patients were most often violent, and patients suffering from bipolar affective disorder (hypomania) most often generally disturbed. Schizophrenic patients were often secluded for threatened, as well as actual harm. Incidents involving other psychoses were not of any specific type but, as Fottrell (1980) also found, a small number of patients were repeatedly involved in violent incidents.

Both Campbell *et al* (1982) and Mattson & Sacks (1978) suggested that self-harm and assault can occur during seclusion. In the present study this was noted on only one occasion, when a male patient demolished the seclusion room.

The timing of incidents is probably a reflection of

the response of non-psychotic patients to external stimuli; psychotic patients may be responding to internal stimuli, with a more random timing of their outbursts.

If the experience, morale, and number of staff on a ward are all low, this may lead to patients becoming disturbed and thus to seclusion rather than other responses, particularly at mealtimes. New patients to the ward are usually at their most disturbed, and of unknown potential; they may be secluded 'to be on the safe side', especially if they are male and their appearance is intimidating. What is perhaps most important is the attitude of nurses, doctors and other ward staff towards the patient, which may partly explain why staff are the commonest victims or why attacks on staff may lead not to reprimands but to seclusion.

From the author's personal experience, it seems that special observation of selected patients, i.e. allocating a nurse to be with one patient only at all times (usually on admission or after a disturbed period), helps to reduce violence and thus the incidence of seclusion.

Guidelines have been published on the management of violent patients (Department of Health & Social Security, 1976; Confederation of Health Service Employees, 1977; Royal College of Psychiatrists, 1980) and recommendations on the practice of seclusion have been formulated, the most widely used probably being those of the Royal College of Nursing (Society of Psychiatric Nursing 1979; Royal College of Psychiatrists, 1982; Jones, 1982; Wilkinson, 1983). Further guidelines from the Mental Health Act Commission are expected.

While there may remain a place for seclusion in general psychiatry, most incidents can and should be managed in other ways, although the prevention of such incidents is even more important. Once seclusion has occurred, it should be for short periods, reviewed regularly, and only rarely without medication.

It is difficult to generalise about seclusion as its use is so relatively rare, the individuals involved so varied, and the published data from this country so lacking. Seclusion is such an embarrassing topic that reports have been scanty and anecdotal, or else simple statements of hospital policy or person pronouncements. The subject deserves further study.

Acknowledgements

I would like to thank Dr A. P. Thorley for helpful comments and Mr T. Furness for statistical advice.

**SOME PEOPLE'S IDEAS ABOUT
ST ANDREW'S ARE AS DATED AS
THIS ENGRAVING**

Established almost 150 years ago St Andrew's has always been in the forefront of psychiatric developments.

In the 1800's it was the first hospital to totally abolish physical restraint. As early as 1927 it opened a separate unit for short stay patients. In the 1980's it has pioneered the application of behavioural methods to the management of a range of disorders including severe brain damage.

Suicide in Young Doctors

J. C. RICHINGS, G. S. KHARA and M. McDOWELL

Fifty-five cases of suicide by doctors under the age of 40 were studied because of concern about deaths among anaesthetists in training. The excess mortality of doctors from suicide was confirmed, suggesting that risk factors associated with being a member of the medical profession continue to operate, although mortality for young male doctors from accidental poisoning is falling. Analysis of the branches of medicine in which the doctors were working showed no definite specialty predominance. There was a somewhat greater risk for women doctors born overseas.

Suicides account for a substantial number of deaths in England and Wales; evidence shows that they are on the increase and that, although the risk is greatest among middle-aged men, the greatest rise recently has been in young people (McClure, 1984; Bulusu & Alderson, 1984). Successive *Decennial Supplements on Occupational Mortality* (General Register Office (GRO), 1958, 1971; Office of Population Censuses and Surveys (OPCS), 1978) for England and Wales have shown relatively high rates of suicide among male members of the medical profession; comparable figures are not available for women doctors because of limitations in the data and methods used for calculating occupational death rates (McDowell, 1983). However, an increased rate of suicide has been reported in women doctors in America (Steppacher & Mausner, 1974). A number of studies have suggested that a doctor's specialty may increase the likelihood of suicide: anaesthetists (Helliwell, 1983), psychiatrists (A'Brook *et al.*, 1967), ophthalmologists (Waterson, 1976), and pathologists (Harrington & Shannon, 1975) have at various times been thought to be particularly vulnerable.

The standardised mortality ratios (SMRs) for male doctors from the post-war Decennial Supplements (GRO, 1958, 1971; & OPCS, 1978) are shown in Table I. The supplement based on the year 1951,

1958) notes that the excess was greatest among the younger male doctors, with SMRs of 400 for the 20-30 age group, 283 for 35-44, 211 for 45-54, and 113 for 55-64 (the SMR for all males in England and Wales is set as 100 for each age group). Similar breakdowns by age were not published for the two subsequent studies (GRO, 1971; OPCS, 1978), but a special tabulation of mortality ratios for suicide in male doctors for 1970-1972 shows excess mortality at all age-groups (273 for age 25-34, 388 for 35-44, 316 for 45-54, and 388 for 55-64). Recent concern over the number of suicides in one particular group of young doctors (Helliwell, 1983) prompted us to undertake a study using more up-to-date information.

Method

The under-reporting of suicides in official statistics has been well recorded (Sainsbury & Jenkins, 1982; Adelstein & Marden, 1975), many will be recorded as open verdicts or accidental deaths, due to the natural reluctance of coroners to enter a verdict of suicide where some possible measure of doubt remains. A wider view of suicide, which includes deaths recorded as 'suicide' (ICD-9 categories E950-E959), 'undetermined' (ICD-9 categories - E980-E989) and 'accidental poisoning by drugs etc' (ICD-9 categories E850-E859) has been proposed by Adelstein & Marden. Although it has been argued that the wider definition adds little to most analyses (Sainsbury & Jenkins, 1982), the presentation and recording of suicide in doctors may vary from that of the general public. In order to avoid any possible bias, both the narrow and wide definitions of suicide have therefore been used in this study.

From death registration records at the OPCS we extracted draft death entry forms for deaths from the three groups of causes above, for medical practitioners under the age of 40 in England and Wales. We covered five years: 1972, 1975, 1979, 1980, and 1982. Suitable data on populations at risk were only available from 1972, and the years chosen were those for which occupation at death had been

coded by OPCS. Each case was checked against detailed data available in the Civilian Doctors' Career Index (CDCI) maintained by the Department of Health and Social Security. The study is based on 55 cases - 36 suicides, eight 'undetermined', and 11 cases of accidental poisoning. Estimates of population at risk were based on data from the CDCI, and both mortality and population figures were cross-classified by sex and country of birth. For most cases we were also able to determine the main medical occupation and hospital specialty, if any.

Mortality ratios were calculated by comparing observed deaths of doctors under 40 with those expected. The expected deaths were derived from England and Wales mortality rate (age 25-39) for the respective causes (and for each of the study years) applied to the population of medical practitioners aged under 40, derived from the CDCI.

Results

The mortality ratios for the wide definition of suicide and its component parts for both male and female practitioners under the age of 40, for all the study years combined, are shown in Table II. Although the numbers of deaths are small, the highest ratios for both male and female doctors

are from 'accidental poisoning with drugs etc'. Ratios for both sexes and by both definitions of suicide are significantly greater than 100. Table III shows mortality ratios for each year of the study, for both the narrow and the wide definitions of suicide. The number of cases in each year is small, leading to quite marked variation between individual years. The mortality ratios for young female doctors are based on a small number of cases, and there is no discernable pattern of a time-trend, but the pattern for young male doctors varies according to the definition of suicide employed.

Mortality under the narrow definition of suicide shows no clear pattern over the years, but there is a marked decline in mortality ratios under the wider definition. Part of this decline is due to a fall in the crude rate of suicides (wider definition) of young male doctors - from 48 per 100 000 in 1972 to 32 in 1982 - but in the same period there has been a steady rise in the national rates for men under 40 (from 14 per 100 000 to 22), and this too has contributed to the decline in mortality ratios. This difference in mortality patterns for young male doctors between the two definitions is almost entirely due to a fall in deaths from accidental poisoning from drugs and other substances, of which there were five in 1972, three in 1975, and none in the subsequent years. Young female doctors, on the other hand, have consistently

TABLE IV
Mortality ratios in England and Wales for the wide definition of suicide in male and female doctors aged 25-39, for the years 1972, 75, 79, 80 and 82 combined, categorised by place of birth

	<i>British Isles</i>		<i>Elsewhere</i>		<i>All place of birth</i>	
	<i>SMR</i>	<i>n</i>	<i>SMR</i>	<i>n</i>	<i>SMR</i>	<i>n</i>
Males	188*	29	172	6	170*	75
Females	186	5	523*	5	274*	10

* $P < 0.05$

higher mortality ratios than their male colleagues (Tables II and III). The crude rate of suicide (wider definition) in young female doctors was in fact less, at 23 per 100 000, than that for young male doctors (31 per 100 000). However, the national suicide rates for women are considerably lower than those for men, thus giving a higher mortality ratio.

The England and Wales SMR for the wider definition of suicide for Social Class I, (Registrar-General's classification), which includes doctors, for men aged 15-44 in 1970-72 (the latest figure available) was 90 (OPCS, 1978). Young persons born outside the British Isles do have a higher risk of death from suicide: SMRs for ages 25-39 for the wider definition of suicide in 1969-73 for these men and women were 169 and 165 respectively (unpublished OPCS data). This suggests that the increased SMR for suicide in doctors is not related to social class.

Table IV cross-classifies the combined years' mortality ratios (wider definition) for each sex with place of birth (British Isles or elsewhere); the higher ratio in young female doctors compared with male doctors is almost entirely due to a very high ratio for the female doctors born overseas. Four of the five cases of young women doctors who were born overseas were registered as suicides, the other one as accidental poisoning. The similarity of the ratio for young male doctors, born in the British Isles or elsewhere, and the young female doctors born in the British Isles suggests a comparable degree of excess risk for the three groups.

Poisonous substances, including drugs, were the cause of death in 39 out of 55 doctors in our study (55% of the male and 90% of the female doctors). Members of the medical profession usually have ready access to drugs, and this probably accounts for the preponderance of this method of suicide. At the time of death, ten doctors were working as general practitioners, twenty-seven were employed in the hospital services, three worked in universities, and one worked in the community health service, the employment of the remaining fourteen was unknown.

By using the wider definition of the population at risk, the crude rates per 100 000 for general practitioners and all hospital specialties were both 23. For the individual hospital specialties, the rates were: anaesthetics 67, general medical 20, surgical 19, psychiatry 39, and pathology 36; these differences should be treated with caution, as the numbers are very small.

Discussion

There is an excess mortality from suicide in both young male and female doctors, using both the wide and narrow definitions; this had been shown previously for male doctors. The mortality ratios based on the narrow definition of suicides do not show a significant trend. The figures are based on a small number of cases, but do suggest that there might have been an underlying trend for the rates to decline since the early 1970s; if this is true, doctors would have decreased their suicide rate against the general tide. Mortality ratios based on the wider definition of suicide show a definite decline in the mortality ratios for young male doctors over the years studied, but there is no such clear evidence for young female doctors.

The overall excess mortality from suicide is not explicable in terms of social class, at least for young male doctors (female social class rates are not available) (Bulusu & Alderson, 1984), which suggests that there are risk factors associated specifically with being a member of the medical profession. Doctors usually have ready access to drugs, and this was a common cause of death for both men and women doctors. This contrasts with the general population, where access to drugs is restricted and where self-destruction by physical means such as hanging and poisoning by vehicle exhaust fumes assumes a more prominent role (Farmer & Rhode, 1980). In 1980, for men in England and Wales, death by poisoning accounted for 30% of total suicides (wider definition), in contrast with hanging, which accounted for 19% of cases. However, poisoning remains the commonest method for women: 56% in England and Wales for 1980 (OPCS, 1982).

The figures given for the individual medical specialties of these doctors must be treated with caution, as the majority of those in the hospital service were still in the training grades, and it is

difficult to be certain that the specialty in which they were working at the time of death was their main working experience or was intended to be their final career choice. The rate for anaesthetists is significantly higher than those in the other specialties. In our study, the suicides of anaesthetists were recorded in one year, but this may have been an atypical year. A study of suicide in anaesthetists in training for the years 1979–1982 (Helliwell, 1983) showed five deaths from suicide in that period: using the target population for anaesthetists for these years, the rate for that study is 39 per 100 000. It also examined each case in depth, showing that the individuals were not under-achieving or showing stress due to the work situation, but that each had a considerable emotional problem which was thought to lead to the suicidal act. We were not able to identify the medical specialty of 14 doctors; it is likely that most of them worked for short periods in either the hospital or general medical services. These doctors could make a considerable difference to the crude rates shown for the two main groups and the individual specialties, so these figures should be viewed with caution.

A doctor's place of birth is relevant to mortality

rates from suicide. Unpublished data from OPCS established that young people from overseas have a significantly higher mortality rate from suicide than those born in the British Isles. For male doctors there appears to be little direct influence of the country of birth on suicide mortality, compared with the experience of all men and women born overseas, but the higher risk of death from suicide of young persons born outside the British Isles does not appear to explain why the ratio for young female doctors born overseas is significantly greater ($P < 0.05$) than the ratio for young female immigrants. This gives cause for concern, and since this ratio exceeded that in all other groups of doctors studied it cannot simply be explained by gender or by ready access to lethal means. It is possible that the feelings of isolation, including separation from the extended family and failure to adjust to a new social environment, coupled with difficulty in obtaining medical posts in this country (Smith, 1980) have contributed to this high ratio. The absolute numbers are small, so the position should be monitored in the future to see if this trend continues.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

CONTEMPORARY ISSUES IN SCHIZOPHRENIA

Edited by Alan Kerr and Philip Snaith

ISBN 0 902241 14 1

Pp 480

£17.50

This book presents a comprehensive selection of re-edited papers published in the British Journal of Psychiatry during the last ten years, together with a number of specially commissioned reviews of current knowledge in schizophrenia. The subject is considered under seven sections: general and historical concepts; classification and phenomenology; organic aspects; genetic aspects; social aspects; treatment; and outcome.

Contemporary Issues in Schizophrenia, published February 1986, at £17.50 postage free. Orders with cheques should be sent to: Editorial Office, Royal College of Psychiatrists, 17 Belgrave Square, London SW1X 8PG.

Relationship of Mood Alterations to Bingeing Behaviour in Bulimia

W. H. KAYE, H. E. GWIRTSMAN, D. T. GEORGE, S. R. WEISS and D. C. JIMERSON

Twelve women with bulimia participated in a study in which they binged and vomited on the day after hospital admission. Caloric intake, time spent bingeing and vomiting, and self-reported mood ratings demonstrated much variation from subject to subject. Both subjective and objective ratings of mood indicated that anxiety decreased more frequently and to a greater extent than depression, both during and after bingeing and vomiting. The present data, obtained in a controlled setting, tend to confirm previous information on binge episodes obtained by self-report from bulimic patients. Bingeing and vomiting episodes may provide bulimic patients with a physiological mechanism for temporarily relieving a dysphoric mood state.

The bulimic symptom complex in women has received much attention in the past decade and has been found to be surprisingly common (Stangler & Printz, 1980; Halmi *et al*, 1981; Pyle *et al*, 1983; Johnson *et al*, 1984). Bulimia has been hypothesised to be related to affective disorders. Patients with bulimia (Pyle *et al*, 1981; Gwirtzman *et al*, 1983; Hudson *et al*, 1983a) and their first-degree relatives (Hudson *et al*, 1983b) often have disturbances of mood and/or a history of substance abuse. Bulimia and affective disorders share certain neuro-endocrine dysfunctions (Gwirtzman *et al*, 1983), and the bulimia symptom complex often responds to anti-depressants (Pope *et al*, 1983; Walsh *et al*, 1984).

Only a few studies, using patient self-report, have examined the relationship between bingeing-purging and mood. The initiation of bingeing appears to be associated with weight control (Chiodo & Latimer, 1983) or stress (Strober, 1984). Several studies suggest that bingeing may serve to relieve tension (Johnson & Larson, 1982; Abraham & Beumont, 1982). The relation between bingeing-purging behaviour and the global depression often associated with bulimia is not clear.

Because patient self-report is not always reliable, we designed this preliminary study to allow observation and documentation of mood during and after bingeing and vomiting episodes. Bulimics rated their mood subjectively while bingeing and vomiting, and for two hours afterwards. Objective mood ratings were performed twice, once before and once after the sequence of bingeing and vomiting. Global mood was measured by standardised subjective and objective ratings some time after the bingeing and vomiting were over.

The mechanisms, biological or otherwise, whereby food intake alters mood are not known. Studies of

animals suggest that carbohydrate foods can produce alterations in certain brain neurotransmitters such as serotonin (Wurtman, 1983), a neurotransmitter also implicated in mood regulation; therefore it is important to determine whether different components of the food consumed, such as carbohydrate, influence mood directly.

Caloric intake and time spent in bingeing and vomiting were documented and compared with mood changes, because we were particularly curious as to whether improvement in mood was the factor responsible for terminating bingeing and vomiting. We therefore instructed patients to binge and vomit until they achieved whatever effect was important to them.

Method

Twelve women who satisfied DSM-III criteria for bulimia were admitted to an NIMH intramural research ward: clinical data for these subjects are given in Table I. All subjects gave informed consent for the study. All patients had a history of bingeing and vomiting at least once per day for three months prior to admission. Bulimics who frequently abused laxatives were excluded. We included one subject with current anorexia nervosa (patient No. 7 in Table I). All other subjects were between 82% and 118% average body weight. (Metropolitan Life Insurance Company, 1959). Three of the subjects had met DSM-III criteria for anorexia nervosa in the past but were currently over 82% average body weight.

Subjects were informed of the study prior to admission and were contacted when possible by the dietitian to determine their choice of binge foods. On the day of admission a physical examination, electrocardiogram and laboratory studies were performed. Many subjects had some degree of electrolyte abnormality, but none so severe as to exclude them from this study. The study was performed on the second day of admission, after medical clearance.

TABLE I
Clinical data for bulimic patients

Patient	Age	Height	Body weight (% of average)			Duration of bulimia (months)	Number of binge-vomit cycles	Depression scores	
			Current	Past min.	Past max.			Beck	Hamilton
1	20 yrs	163 cm	100%	75%	104%	46	1	26	5
2	23 yrs	165 cm	94%	86%	118%	63	1	80	30
3	21 yrs	161 cm	101%	71%	105%	54	2	29	23
4	23 yrs	167 cm	87%	78%	94%	66	2	53	46
5	29 yrs	165 cm	94%	90%	139%	144	2	4	2
6	27 yrs	162 cm	100%	91%	112%	102	3	17	16
7	31 yrs	168 cm	62%	61%	131%	85	3	65	14
8	23 yrs	152 cm	95%	84%	115%	85	3	6	5
9	20 yrs	166 cm	93%	88%	123%	36	4	39	13
10	20 yrs	165 cm	118%	93%	156%	36	4	1	1
11	25 yrs	159 cm	108%	88%	112%	144	4	41	13
12	26 yrs	168 cm	83%	68%	133%	42	5	48	28
Mean	24 yrs	163 cm	95%	81%	120%	75		34	16
S.E.M.	1	1	4%	3%	5%	11		7	4

Because bulimics often prefer isolation during bingeing, we decided to allow them to binge and vomit unobserved in a ward room, but with a physician immediately outside the door. On the day after admission, subjects fasted from midnight. They were placed alone in a ward bedroom with adjoining toilet facilities. At 9.00 a.m. an intravenous line was established. At 10:00 a.m. base-line mood ratings were obtained and the first blood sample drawn. Subjects were then given their first tray of food. A physician entered the room after each binge and vomit to supervise the self-report ratings and draw blood. (Our biological findings will be reported elsewhere.)

In an attempt to replicate the home environment, patients were permitted to take as much time as they desired to binge and vomit. We tried to supply as many as possible of the foods that subjects requested. Each subject was offered a tray of 5000–6000 kcal of food. The amount of food consumed was estimated by the dietitian by methods described elsewhere (Petersen *et al*, 1986). Patients were instructed to continue to binge and vomit until they had achieved whatever 'desired effect' determined the point at which they stopped at home, but with the exception of one subject who binged and vomited five times, we terminated the study after four binge-vomit episodes even if the 'desired effect' had not occurred.

Our comparison group comprised seven healthy female controls without personal or family history of psychiatric illness. Each was given a large (900–1700 kcal) test meal.

The controls did not vomit, and consumed their entire test meal at one sitting over one hour.

Mood was quantified by several methods. All 12 bulimics and all 7 controls self-rated changes in mood and other factors on a 7-item visual analogue scale before eating. This subjective rating was repeated by the bulimics after each binge-and-vomit, and at hourly intervals after termination of the last binge-vomit cycle (see Figure 2). The same scale was given to the controls immediately after their test meal and twice more at hourly intervals. Two psychiatrists rated seven of the bulimics on the Brief Psychiatric Rating Scale (BPRS) (objective rating) before they were given any food and again about 20 minutes after the last binge-vomit cycle. BPRS ratings for the two raters were averaged for each bulimic. The Beck Depression Inventory (Beck *et al*, 1961), the Hamilton Depression Scale (Hamilton, 1960) and the Montgomery-Asberg depression rating scale (Montgomery & Asberg, 1979) were administered by one rater within two days of subjects completing the bingeing and vomiting study.

Results

Caloric intake and binge-vomit patterns

The caloric intake per binge and the time spent bingeing, vomiting, or resting between cycles varied between subjects

FIG. 1. Time course, caloric intake, and changes in subjective mood ratings during and after bingeing and vomiting. The horizontal dimension of the striped box indicates time spent bingeing, the vertical dimension indicates caloric intake per binge (0–5000 kcal). The horizontal dimension of the black box indicates time spent vomiting. Visual analogue mood ratings for anxiety (open circles) and depression (black dots) are indicated for each patient (100 = anxious, depressed; 0 = calm, happy). Patient 3 missed one rating.

(Fig. 1). However, every subject who engaged in multiple bingeing and vomiting cycles appeared to have a consistent pattern of caloric intake from binge to binge, and of time spent bingeing and vomiting. The mean duration of each binge was 30 minutes (s.e. 10) and the mean vomit duration was 13 minutes (s.e. 9). The mean individual binge consisted of 3500 ± 1338 kcal, and total caloric intake over the whole cycle of binges had a mean of 9360 ± 5275 kcal. Macronutrient distribution was $52\% \pm 10\%$ carbohydrate, $37\% \pm 9\%$ fat, and $11\% \pm 2\%$ protein.

Subjective mood ratings

Before eating, bulimic subjects rated themselves as significantly more depressed, more anxious, less hungry, and less confused than controls (Fig. 2). After bingeing, bulimic subjects showed a significantly greater decrease in anxiety,

and a smaller decrease in hunger, than the controls did after their meal. Neither group showed an overall change in depression ratings.

Each bulimic appeared to have a unique pattern of changes in mood on the self-rating scales during and after binge–vomit cycles (Fig. 1). The great variation between individuals in patterns of depression and anxiety are apparent when graphed with caloric intake and time spent bingeing and vomiting. For example, subjects 6, 7, and 8 each had three cycles of bingeing and vomiting. Subject 6 had her greatest improvement in anxiety after her second binge and vomit, but less change in depression; and her anxiety and depression increased after the third binge and vomit. Subject 7 had a substantial reduction of both depression and anxiety after her third binge and vomit. Subject 8 had a step-wise reduction in anxiety and depression after each binge and vomit.

FIG. 2. Comparison of bulimic patients ($n=12$) and healthy control women ($n=7$) on visual analogue self-ratings. Seven factors were self-rated at base-line ('pre-binge'), ratings were repeated 'post-binge' (immediately after the last binge and vomit for bulimics, after the test meal for controls), and again at 1 and 2 hours 'post-binge'. Bulimics are indicated by black circles, healthy controls by open circles. 'a' indicates a significant difference ($P<0.05$) between bulimics and controls by repeated-measures ANOVA, 'b' a significant difference in group $\times$ time interaction (difference in pattern of response between groups).

On the basis of our clinical impressions during the study, we considered a subjective score meaningful only if there was more than 50% change from base-line. Because of heterogeneous response on the self-rating scale, we categorised changes in mood into three patterns:

1. Of twelve subjects, six (numbers 4, 6, 8, 10, 11, 12) had a reduction of 50% or more in depression and/or anxiety between cycles of bingeing and vomiting: even

though their mood improved these subjects continued to binge and vomit. After all the cycles of bingeing and vomiting were over, most of these subjects had greater residual depression than anxiety.

2. Four subjects (numbers 1, 2, 7, 9) had an improvement in anxiety and/or depression of at least 50% at the time they stopped bingeing and vomiting.
3. Two of the twelve subjects (numbers 3 and 5) did not achieve any improvement in mood either during or after bingeing and vomiting

A substantial decrease in anxiety occurred at some point during or after the binge-vomit cycles in eight of the twelve bulimics, whereas only four had a substantial reduction in depression. Base-line self-rating analogue scores for anxiety and depression were positively correlated ($r=0.643$, $P=0.02$, $n=12$), but there was no significant correlation ($r=0.480$, $n=12$) between subjective anxiety and depression after the end of the last binge-vomit cycle. Base-line subjective and objective anxiety scores were significantly positively correlated ($r=0.772$, $P<0.05$, $n=7$), but base-line depression scores were not.

BPRS ratings

The last seven bulimic subjects to participate in this study were assessed with the BPRS at 10:00 a.m. (base-line) and again 20 minutes after the end of bingeing and vomiting. Paired t -tests revealed a significant reduction in anxiety ($t=3.74$, $P<0.01$) but not in depression (Fig. 3). Two other measures on the 24-item BPRS were significantly reduced: guilt ($t=3.07$, $P<0.05$) and tension ($t=4.8$, $P<0.01$).

Global depression ratings

Bulimics had a wide range of depression scores on the Beck Depression Inventory and the Hamilton Depression Scale (Table I). Montgomery-Asberg depression scores were of a similar magnitude. There were no correlations between base-line or subsequent scores on the self-rating or BPRS depression scales (completed on the day of the binge study) when compared with the Beck, Hamilton, or Montgomery-Asberg depression rating scales (completed later). Hamilton, Beck, and Montgomery-Asberg ratings were significantly correlated with each other at the $P<0.01$ level.

Relation of caloric intake to mood

There was a weak positive correlation between rate of food consumption (calories per minute) during the binge-vomit period and both initial Beck scores ($r=0.653$, $P<0.05$, $n=12$) and Hamilton scores ($r=0.546$, $P=0.07$, $n=12$). Rate of caloric consumption showed a negative correlation with the percentage of carbohydrate in the chosen meal ($r=-0.591$, $P<0.05$) and a positive correlation with the percentage of fat ($r=0.554$, $P=0.06$). There was no relationship between alterations in depression and anxiety during the binge study and the subject's total caloric consumption, or her relative preference for carbohydrate, protein, or fat.

FIG. 3. Brief psychiatric rating scale (BPRS) scores for anxiety and depression in 7 bulimic subjects. Scores just before patients began bingeing and vomiting ('pre-binge/vomit') are compared to scores 20 minutes after they finished the last cycle of bingeing and vomiting ('post-binge/vomit').

Discussion

The results of this study demonstrate heterogeneous patterns of mood changes during and after bingeing and purging in bulimic patients. Abraham and Beumont (1982) found that 34% of patients got relief from anxiety *during* the cycles of bingeing and 66% reported freedom from anxious feelings *after* the cycles of bingeing had concluded. The corresponding subjective reports of decreased anxiety in our study (50% during bingeing, 67% after bingeing) were similar and were confirmed by objective ratings. Johnson & Larson (1982) did not measure anxiety but reported a general worsening of affective state during a binge in terms of greater guilt, shame and anger: after the binge-purge episodes were over, the patients in the Johnson & Larson study were sadder, drowsier, weaker, and more bored than usual. Similarly, many of our subjects remained depressed during and after bingeing and vomiting. The DSM-III states that although eating binges may be pleasurable, and vomiting often reduces post-binge anguish, depressed mood and self-deprecating thoughts follow eating binges. While our results generally support this statement, we would add that a reduction in anxiety or tension often occurs during or after bingeing and vomiting.

Episodes of bingeing and vomiting have been described as being associated with, or precipitated by, dysphoria or stress (Abraham & Beumont, 1982; Johnson & Larson, 1982; Strober, 1984). Our study was performed irrespective of pre-binge mood state. While it may be assumed that the bulimics were

stressed since this study was done on the day after hospital admission, the BPRS ratings only indicated mild-to-moderate anxiety and tension. In-patient studies, by their very nature, may produce artifacts because they take place in an environment different from that in which bingeing and vomiting usually occur. It is difficult to know how much environmental effects may have altered base-line mood and responses in our study. The bulimics did volunteer the information that they might not have begun a binge in these circumstances if on their own, but once in the midst of bingeing and vomiting they described their responses as fairly typical. In spite of these factors, many subjects had a decrease in dysphoria with bingeing and vomiting. The self-report literature suggests that many bulimics have a similar response in their more usual settings.

It is not clear what stimuli cause the subject to terminate an episode of bingeing and vomiting. Only 4 of our 12 subjects had an improvement in anxiety and/or depression (compared with base-line) at exactly the time they ended bingeing and vomiting. It is possible that we may not have rated the most significant change in mood: some subjects appeared to be giddy, silly, or somewhat intoxicated at the time they volunteered to stop bingeing and vomiting. It is also possible, as Johnson & Larson (1982) have suggested, that patients entering a treatment programme after years of bulimia may no longer be getting relief of symptoms by bingeing and purging. As with substance abuse, tolerance may develop over time: bingeing is then needed to maintain a dependency rather than to get high. Our bulimics had been

symptomatic for three or more years. We did not find relationships between duration of bulimia and observed response, but perhaps studying bulimics much earlier in the course of the disease would reveal more consistent mood changes.

This study confirms patient self-reports as to the number of calories and proportions of carbohydrate, fat and protein consumed during binges, as well as confirming that bulimics do not necessarily consume high-carbohydrate foods but may also consume high-protein or high-fat foods (Mitchell *et al*, 1981; Abraham & Beumont, 1982). Our data tend to suggest that the rate of consumption (45–166 kcal per minute) bears some relationship to the type of food eaten and to mood. The bulimics who ate the fewest calories appeared to preferentially select carbohydrate and to avoid fat-containing foods, whereas those that consumed the most calories per minute had the opposite relationship. Whether the most rapid eaters preferred fat-containing foods or just ate any available food is not clear since we did not give the bulimic subjects an unlimited supply of food to choose from. Food preferences during bingeing might reflect differences in hypothalamic neurochemical control of eating behaviour, since the choices of fat and carbohydrate may be regulated by separate systems (Leibowitz, 1980). Those bulimics that consumed the most calories per minute had the greatest depression ratings on global mood scale. If such a finding can be replicated it might suggest that endogenous neuromodulators that influence the rate of eating may differ between depressed and non-depressed bulimic subjects.

While bingeing and purging may often produce an immediate but brief reduction of anxiety and hunger, the relationship between bingeing and depressed mood is less clear. In this study many subjects were not substantially depressed (according to their global mood ratings) and only some of those that were depressed had a reduction of depression during bingeing. Thus bingeing does not appear to be used to 'self-medicate' an underlying depression. Alternatively, depression could be a secondary manifestation related to chronic bingeing and vomiting (Johnson-Sabine *et al*, 1984). An increase in negative mood states has been reported on days when patients engaged in bingeing and/or purging (Johnson-Sabine *et al*, 1984). Johnson & Larson (1982) have suggested that bingeing and purging might be a form of substance abuse, with extremes of food intake and/or vomiting used to improve mood briefly. The immediate brief rewards associated with bingeing and vomiting may be followed, at other times of the day, by periods of withdrawal or rebound that account for the increased dysphoria on global mood

scales. Thus bulimics may become trapped in vicious cycles of binge-induced reductions of dysphoria alternating with rebound, i.e. withdrawal-induced increase in dysphoria.

It is possible that some bulimics, particularly those without depression or any anxiety disorder, adopt binge-vomit cycles to counter a psychological or biological predisposition towards obesity. A few studies have suggested that bulimics might easily become obese (Pyle *et al*, 1981; Fairburn & Cooper, 1984). Similarly, it has been suggested that bingeing and purging might be a short-term solution to counter a drive to eat and gain weight (Chiodo & Latimer, 1983). Several studies have suggested that genetic vulnerability to obesity might be inherent in relatives of those with normal-weight bulimia (Fairburn & Cooper, 1984; Mitchell *et al*, 1981). In the present study, all three (25%) of the bulimics who had low global depression scores on admission (numbers 5, 8, and 10) had a past history of weight equal to or greater than 115% average body weight, suggesting that they might have a tendency towards obesity.

This study is, to our knowledge, the first naturalistic investigation using behavioural ratings during bingeing. Several methodological problems have appeared that should be borne in mind in future investigations. Several authors (Walsh *et al*, 1984; Johnson-Sabine *et al*, 1984) have suggested that many bulimics do not have a major depressive disorder, but rather have a fluctuating anxiety or tension disturbance: such behaviour would not be accurately measured by the standardised ratings that we used. We have frequently noticed alexythemia in bulimics; thus they may be poor witnesses to their own behaviour. Lastly, 'a reduction in anxiety' may not accurately describe the effects of bingeing, as some bulimics appeared to be intoxicated or 'spaced out'. Future studies should employ a broader range of objective behavioural ratings.

In summary, we have demonstrated in this study that patients with chronic symptoms of bulimia generally experience more marked reduction in anxiety than in depression during the course of bingeing and vomiting episodes. While patterns of bingeing and vomiting appeared to remain stable for each individual, different subjects demonstrated a wide range of mood responses. Further study of the mechanisms by which bingeing and vomiting alter mood states may be expected to contribute to the treatment of bulimic symptoms.

Follow-up of Agoraphobic Patients Treated with Exposure In Vivo or Applied Relaxation

L. JANSSON, A. JERREMALM and L. G. ÖST

The present study describes the results of a 7-month and a 15-month follow-up of 32 agoraphobic patients treated with exposure *in vivo* or applied relaxation. During the follow-up period, all patients were given self-exposure instructions. Assessments were made in three response systems—subjective-cognitive, behavioural, and physiological—at the follow-up points. The study showed overall maintenance of treatment results in all three response systems for exposure-treated patients. For applied relaxation/self-exposure, there was a relapse on heart-rate at 7 months for physiologically reactive patients, but the improvement was regained at the 15 month follow-up. Furthermore, a large proportion of the total improvement occurred during the follow-up period: 36% and 22% for exposure and applied relaxation/self-exposure respectively. The proportion of patients reaching a clinically significant improvement was 50% at the end of treatment and 66% at the 15 month follow-up.

Different behavioural treatments have been recorded as having a powerful immediate effect on agoraphobia, with a mean of 63% of the patients being much improved after treatment by the most widely used method, exposure *in vivo* (Jansson & Öst, 1982). However, the long-term effects of behaviour therapy on agoraphobia are more uncertain, since few studies report on the long-term results (see Table I).

Marks (1971) reported the follow-up results on 36 agoraphobic patients treated with systematic desensitisation and other forms of psychotherapy. Four years after treatment the results were maintained on phobia ratings made by the patients and their therapists. Emmelkamp & Kuipers (1979) assessed 70 agoraphobic out-patients with self-report forms at four years after treatment with variations of exposure therapy. They found that the improvements were maintained during the follow-up period.

Four studies have used independent assessor ratings of agoraphobic symptoms, giving more credence to the follow-up results. Hafner (1976) administered self-report assessment forms to 39 patients treated with *in vivo* exposure one year after treatment, and found that one third of them were unimproved or worse at follow-up. However, on independent ratings of agoraphobic symptoms the improvements were maintained at one year. Munby & Johnson (1980) assessed 66 patients at 5-9 years after treatment, and they also used both self-report and independent assessor ratings. Both these

measures showed that the improvements were maintained, and no evidence of symptom substitution was found. Another investigation also used self-report and independent assessor ratings for 40 agoraphobic patients treated with imipramine or exposure (Cohen *et al*, 1984). Two years after treatment, two thirds of the patients remained improved or much improved in their phobias.

It seems that the effects of behaviour therapy for agoraphobia are maintained for several years after treatment, as evidenced by both subjective measures and independent ratings. However, little is known about the long-term stability of the behavioural changes in agoraphobic patients, since only two unpublished studies have included a behavioural test at follow-up. Burns *et al* (1983) reported the follow-up results at eight years of 18 out of 32 patients treated with different behavioural methods. At the follow-up point the patients were assessed by self-report, independent assessor ratings and a behavioural test. In general, the improvements were maintained on all three measures.

The primary purpose of the present investigation was to study the long-term effects of behavioural treatment on self-report, behavioural and physiological measures of agoraphobia. A secondary purpose was to compare the amount of change immediately after treatment with that after the follow-up period, and also to determine the clinical significance of the improvements at the different points of assessment.

TABLE I
Follow-up results of controlled studies on behavioural treatments of agoraphobia

Authors	n at follow-up	% of n at treatment	Measure ¹	Results			Total improvement ² %	Proportion of improvement during follow-up ³ %	% receiving further treatment

Method

Patients and design

Details of the original design and treatment have been described by Öst *et al.* (1984). The subjects were out-patients at Ulleraker Mental Hospital, and fulfilled the following criteria.

- They were aged 20-60.
- The major presenting complaint was fear of, and avoidance of, being alone in public places from which escape might be difficult or help not available in case of sudden incapacitation.
- They have no other psychiatric problem in need of immediate treatment.
- If any medication was used the intake was to be held constant during the study
- They indicated their willingness to participate in the study for a period of three months.
- They received no other kind of psychiatric or psychological treatment except for the ongoing medication during the treatment.

Of the 40 patients that were included in the study, 38 were women and 2 were men. The sample's mean age was 36.2 years (range 25-52) and the average duration of the phobia was 8.3 years (range 1-28). Twenty-nine of the patients (73%) experienced panic attacks outside their phobic situations. Only 7 were drug-free at the start of treatment, while 20 were taking benzodiazepines, 11 some combination of benzodiazepines and other psychoactive drugs, and 2 were taking neuroleptics

Each patient was first classified as a behavioural or a physiological reactor depending upon their reactions on a behavioural test (Öst *et al.*, 1984). The patients were then randomly assigned to receive 12 sessions of either exposure *in vivo* (E) or applied relaxation (AR). The applied relaxation included practical training in how to use relaxation as a coping technique in difficult situations. The treatment was carried out by two experienced therapists with relevant training and five years of clinical experience in behaviour therapy.

A maintenance programme was delivered at the final session consisting of the following strategies: a list of high-risk situations; an individualised strategy in case of a set-back; a monthly self-monitoring schedule for self-exposure; and monthly telephone contacts with the therapist (Jansson *et al.*, 1984). All patients received this self-exposure component during the first five months of follow-up.

Assessment

All of the following assessments were made before and after treatment and (on average) 7 months and 15 months after the end of treatment.

Self-report. The patients completed a Swedish version of the Wolpe & Lang (1964) Fear Survey Schedule (FSS-III). To assess the specific agoraphobic reaction they filled out the Agoraphobia Scale (constructed by the authors) with twenty common agoraphobic situations, estimating both anxiety in entering the situation and degree of avoidance of the situation. Also, the patients filled out the Agoraphobia Questionnaire (Zitrin *et al.*, 1980) and panic attacks were

assessed with the Acute Panic Inventory (Zitrin *et al.*, 1980). The physiological reactions in anxiety-provoking situations were measured with the Autonomic Perception Questionnaire (Mandler *et al.*, 1958). To tap negative thoughts during the behavioural test the patients rated on a scale from 0 to 4 the frequency of ten negative self-statements. To measure the patients' degree of depression and marital satisfaction the Beck Depression Inventory (Beck, 1967) and Maudsley Marital Questionnaire (Crowe, 1978) were administered. Lastly, the patients also rated an individual hierarchy of the 15 agoraphobic situations used in the behavioural test, on a scale from 0–100 in anticipated anxiety.

Behavioural measure. A behavioural test was conducted: each patient was asked to enter real agoraphobic situations unaccompanied. From an individual hierarchy of 15 situations, the patients entered frightening situations until they failed or refused to enter two consecutive situations. The request to enter these situations was presented with emphasis on doing their utmost to provide a realistic picture of their performance and their physiological reactions in the phobic situation. At the post-treatment test the patients were asked to enter both the most difficult situation they had performed at the pre-treatment test and then to try the most difficult situation that they would dare to try after treatment. The test continued in the same way as before: until the patient failed or refused to enter two consecutive situations, or performed the most difficult situation of the hierarchy. The dependent behavioural measure was the percentage of situations completed.

Self-rating of anxiety. During the behavioural test the patients carried a portable ECG-cassette recorder (Medilog 4-2, Oxford Instruments) which also recorded their verbal ratings of anxiety every 2–5 minutes depending on the total estimated time in the phobic situation. The cue for the anxiety rating was a signal from a portable timer, set for the time intervals chosen for the situation. A microphone was attached to the patient's collar to record what was said in the situation as well as sounds from the surroundings.

Physiological measure. The patient's heart-rate was continuously recorded during the behavioural test through one of the four channels on the portable tape recorder. The patient's resting pulse was recorded while the patient was both seated and walking around for five minutes during the screening interview. In this way, the patient's Δ heart-rate (difference between resting pulse and heart-rate in the most difficult phobic situation) could be calculated.

Clinically significant improvement

In order to assess if the degrees of improvement shown by the patient's were clinically significant (Hugdahl & Öst, 1981) the criteria developed by Jacobson *et al.* (1984) were used. According to these, a patient's score on the outcome measure must fall outside the range of the agoraphobic population, where the range is defined as mean ± 2 s.d. As there are no norms for agoraphobic patients on the measures used in this study the sample's pre-treatment values were used. The criteria which had to be fulfilled were as follows: on the behavioural measure the patient had to complete 73% of the situations; the Δ heart-rate must not

exceed $+0.5$ beats/min, and the self-rating of anxiety had to be 0. An overall criterion was also constructed, according to which a patient had to be improved on any two of the three criteria above.

Results

Four patients dropped out from the study and did not complete the original treatment. Another three patients were not available for the 7 month follow-up, leaving 33 patients, 32 of these were available for the 15 month follow-up. The division of subjects into behavioural and physiological reactors did not yield significant differences in treatment effects for exposure *in vivo* and applied relaxation/self-exposure (Öst *et al.*, 1984), consequently the two response patterns were combined and data presented for the two treatment methods only.

Within-group changes

Student's *t*-tests for independent samples were computed to analyse the differences between pre-treatment and post-treatment testing, post-treatment and 7 month, and between 7 month and 15 month follow-ups.

Self-report measures. Both groups improved significantly after treatment on most of the measures. E on seven and AR on nine of the ten measures (see Öst *et al.*, 1984). A table of the complete data can be obtained from the authors.

At the 7 month follow-up, all self-report measures showed that the improvements were maintained for the exposure group. There were no significant differences between post-treatment test and the 7 month follow-up on any of the self-report inventories for those patients receiving exposure *in vivo*. For the applied relaxation/self-exposure group, all but two of the self-report inventories showed maintained improvements. On the Fear Survey Schedule there was a further significant deterioration ($P < 0.001$), and on the Acute Panic Inventory there was a significant deterioration ($P < 0.05$).

At the 15 month follow-up there was a significant further improvement on several of the self-report measures for the E group: Agoraphobia Scale (Anxiety) ($P < 0.05$), Individual Hierarchy ($P < 0.05$), Acute Panic Inventory ($P < 0.05$), APQ (Specific) ($P < 0.05$), and the Negative Thought Index ($P < 0.01$), on all other inventories the improvements were maintained but without further improvement. For the AR group there was a significant further improvement from 7 to 15 month follow-up on the Individual Hierarchy ($P < 0.01$), APQ (Specific) ($P < 0.01$) and on the Negative Thought Index ($P < 0.05$), while the other scales showed a maintained improvement.

Behavioural measure. The results on the behavioural test at 7 month and 15 month follow-ups showed a maintained improvement for both groups: there were no significant differences for either group between the results at post-treatment testing compared with 7 month follow-up, or between situations performed at 7 month and 15 month follow-up.

Physiological measure. There was a steady and continuing improvement for the exposure-treated patients in heart-

rate, responding from pre-testing, across post-testing and 7 month follow-up to the 15 month follow-up. No significant differences, however, were found between post-treatment testing and 7 month follow-up, or between 7 month and 15 month follow-up. However, for the AR group there was a significant increase in Δ heart-rate at the 7 month follow-up compared with post-testing ($P < 0.001$). This increase in physiological reactivity occurred mainly among the physiologically reactive patients. There was a significant difference between physiological (mean = 27.5) and behavioural reactors (mean = 0.8) on Δ heart-rate at 7 month follow-up ($P < 0.01$). At 15 month follow-up, however, there was again a significant improvement in Δ heart-rate compared with the results at 7 month follow-up ($P < 0.01$).

Self-rating of anxiety. Both groups improved significantly after treatment regarding the degree of anxiety experienced during the behavioural test. The E group continued to improve somewhat at the 7 and 15 month follow-ups. The AR group, however, displayed a significant deterioration ($P < 0.05$) at 7 month follow-up, paralleling that seen in the physiological measure. At the 15 month assessment the group's mean was again down at the post-treatment level.

Between-group comparisons. Analyses of variance (split-plot design) were computed to investigate between-group differences. These showed that the two treatment groups were equal on 10 of the 13 measures. Significant F values for the group factor were obtained on the Anxiety ($P < 0.05$) and Avoidance ($P < 0.05$) sections of the Agoraphobia Scale, and on the Agoraphobia Questionnaire ($P < 0.05$). Subsequent Tukey tests on the Agoraphobia Scale (Anxiety) showed that the AR group was better than the E group at the 7 month follow-up. On the Avoidance part, the AR group was better than the E group at the 15 month follow-up. Finally, on the Agoraphobia Questionnaire, the difference between the groups was due to a significant pre-treatment difference, which disappeared when analysis of covariance was used.

Improvement during treatment and follow-up. There was a large variation between the different measures, expressed as percentage change from pre-treatment values, with 13% for the E group on the Maudsley Marital Questionnaire (items 1–20) and 98% for the AR group on Δ heart-rate as the extremes. The means across all measures were 56% for the E group and 68% for the AR group.

If the improvement is divided into that occurring during treatment and that occurring during follow-up, the E group shows a continued improvement on all measures. The AR group, however, improved further on 11 of the 13 measures, the two exceptions being Δ heart-rate and Acute Panic Inventory. The proportion of each group's total improvement that occurred during follow-up was 36% for the E group and 22% for the AR group.

Clinical significance of the improvements

The proportion of patients who had improved to such an extent that it could be considered clinically significant is higher on the behavioural measure than on the subjective and the physiological measures. For exposure-treated patients, 59%, 65% and 71% were clinically improved on this measure directly after, at 7 month and at 15 month

follow-up respectively. For relaxation/self-exposure treated patients, the corresponding figures were 58%, 67% and 83%. For the three forms of measure taken overall there is a tendency for AR to yield a higher proportion of improved patients (AR: 58%, 50%, 72%; E: 41%, 47%, 59%). When the two groups are taken together, 50% are clinically improved at the end of treatment; this figure is increased to 66% at the 15 month follow-up. A comparison of the 15 month with the post-treatment outcome showed that only one patient had relapsed, while 17 had maintained their improvement and 6 had changed from not improved to clinically improved.

During the follow-up period eight patients (25%) received further treatment, five from the original exposure group and three from the applied relaxation/self-exposure group. All patients received exposure *in vivo* for 3–10 sessions (mean = 5). However, four of these patients showed no improvement at any assessment point and were clearly treatment 'failures' in spite of further treatment. Another changed from clinically improved to not improved at the 7 month follow-up, and requested further treatment, which led to his regaining the status of clinically improved at the 15 month assessment. The remaining three patients, who were not improved at post-treatment, changed to clinically improved at follow-up as a result of obtaining further treatment.

Discussion

This is, to our knowledge, the first published study which reports follow-up results for subjective, behavioural and physiological measures. The study showed that the improvements on subjective and behavioural measures were maintained up to 15 month follow-up for exposure-treated patients, and that there was a non-significant trend of continuing improvement in anxiety-ratings and Δ heart-rate among physiologically reactive patients at 7 month follow-up. However, at 15 month follow-up the improvements in all the three response systems were maintained. One possible explanation for the deterioration at 7 months for the AR group could be that they had difficulties with continuing to practice and with applying relaxation techniques during the first follow-up period. However, because of the maintenance programme, which involved self-exposure practice, the behavioural gains were maintained and eventually resulted in a satisfying long-term result at 15 month follow-up. It could be that physiologically reactive patients treated with applied relaxation need an individually tailored maintenance programme containing prompts to continue to practice and to apply relaxation techniques. These specific elements could be incorporated into a standard maintenance programme which is more oriented towards self-exposure (Jansson *et al.*, 1984). This investigation shows a change on the behavioural measure (E group 61%; AR group 72%) which is comparable with the

71% found by Burns *et al* (1983). Also, the changes in ratings of anxiety are in the expected range (E group 57%; AR group 66%).

However, when looking at all the outcome measures taken together, it was found that 36% and 22% of the improvements for exposure and applied relaxation/self-exposure treated patients respectively occurred during the follow-up period. These are more promising results than usually found in follow-up studies (see Table I, where the figures range from -14% to +25%). The findings of a continuing improvement at follow-up is encouraging; one possible explanation for it could be the maintenance programme employed in this study. Self-exposure alone has been found to be as effective as therapist-directed exposure (Gosh *et al*, 1984), and it therefore seems reasonable to assume that the self-exposure component of our maintenance programme was responsible for the continuing improvement found in this study. Therapy with agoraphobic patients

should contain a maintenance programme of self-exposure for at least the first half-year after treatment to ascertain continuing improvement. However, further research is needed on how to administer an effective maintenance programme.

The proportion of patients having a clinically significant improvement was surprisingly high (66%) in the present study. These results give further credence to the clinical usefulness of the treatments used. It is suggested that future studies in the treatment of phobias should use the same way of determining clinical significance (Jacobson *et al*, 1984), so that a more universal way of comparing results will be possible.

Depression and Anxiety in Patients Undergoing Diagnostic Investigations for Head and Neck Cancers

A. D. M. DAVIES, C. DAVIES and M. C. DELPO

Patients attending a regional head and neck Oncology Unit were assessed for depression and anxiety (using the Leeds self-assessment scales) before diagnostic biopsy investigations. At the time of the assessments, neither patients nor investigators knew the biopsy results. Patients whose biopsies subsequently proved positive (showing the presence of a tumour) had significantly higher depression scores than those whose biopsies were negative. Differences in mean anxiety scores did not differ between groups. It is suggested that depression is part of the clinical picture of head and neck cancer.

Interest in the psychological concomitants of cancer has increased in recent years (Greer & Silberfarb, 1982; Feinstein, 1983; Wellisch *et al*, 1983; Manos & Christakis, 1985). Five areas of psychological research have been identified: the psychological morbidity of cancer and its treatments; precursors of the disease; the relation of psychological characteristics to outcome; psychobiological studies; and intervention studies (Greer & Silberfarb, 1982). In head and neck cancer psychological research has focused on the first area, especially on the quality of life of patients following treatment (Olson & Shedd, 1978; Shedd *et al*, 1980; Morton *et al*, 1984). Morton *et al* report that 40% of patients treated for buccopharyngeal cancers satisfied the DSM-III criteria (American Psychiatric Association, 1980) for depression six months after active treatment ended; i.e. depression is part of a pattern of residual disability in these patients. Depression was not related to the type of cancer treatment received, and was itself largely untreated. Massie & Holland (1984) point out that depression in cancer patients is under-diagnosed and undertreated partly because it is believed to be reasonable for cancer patients to be depressed and partly because it is believed that all cancer patients are depressed from the start of their illness. It is not known what proportion of patients are depressed at the beginning of their illness, nor at what stage (if any) depression deepens.

In order to investigate mood disorder from the start of the patient's hospital attendance, mood levels were studied in a group of patients undergoing biopsy as part of a procedure to investigate possible buccopharyngeal tumours. The study was carried out in the same unit as was the work of Morton *et al* cited above, but deals with the early contact of patients with the unit.

Method

Sample

Seventy-five patients (46 men and 29 women) admitted to a regional head and neck oncology unit for diagnostic investigations were given the Leeds scales for self-assessment of anxiety (SAA) and depression (SAD) (Snaith *et al*, 1976); data from the General Health Questionnaire (Goldberg, 1978) were available for 44 patients. Patients were referred from a variety of sources, including general medical and dental practitioners and other hospital departments, and were examined in an out-patients clinic. If there was any suspicion that the patient had a neoplasm, arrangements were made for a 48 hour in-patients stay, during which time a biopsy was carried out. The psychological interview was carried out during this period, on the day before the biopsy investigation.

Data were discarded for three patients (one was discharged before biopsy, one did not reattend, and one had a pre-existing psychiatric disorder); analysis of data was based on the remaining 72 patients. The sample was collected in two stages, each part of separate larger studies (DelPo, 1985), but using the same procedures. There were 18 men and 10 women at stage 1 (mean age 51.9, s.d. 16.0), of whom 17 had a negative biopsy result (i.e. no evidence of a malignant neoplasm was found); the other 11 patients examined had evidence of a malignant buccopharyngeal tumour. Six of the 11 patients were suffering recurrence of a previously treated neoplasm. At stage 2 there were 44 patients, 26 men and 18 women (mean age 54.0, s.d. 8.5), 17 of whom had no evidence of malignancy and 27 of whom were found to be suffering from a buccopharyngeal cancer.

Mood measures

The Leeds scales are self rating scales with four alternatives provided for each of 15 statements, e.g. "I feel scared or frightened". Possible replies are "Yes, definitely"; "Yes, sometimes"; "No, not much" and "No, not at all". Since some of the patients were elderly or of low educational level, the paper and pencil format was modified; all items and

response categories were retained, but the items were read out by an interviewer. The interviewer, a psychologist, went through each item with the patient and ascertained the response that the patient said best fitted what he or she felt.

The scales provide a six item anxiety scale and six item depression scale, with a 'general' and a 'specific' measure for each. The general measures are designed to be used as indicants of severity of symptoms in patients who have not received a primary diagnosis of affective illness, this is the measure appropriate for the present study (The 'specific' measure is concerned with severity of diagnosed affective illness.) The maximum score possible for depression (SAD) and for anxiety (SAA) is 18. The recommended cut-off is between 6 and 7, and scores on each subscale above 6 are regarded as indicating anxiety or depression (Snaith *et al*, 1976). (In the present study the Leeds scales were used to investigate mood, not as a diagnostic tool.) The General Health Questionnaire (30 item version) was scored according to the bimodal method recommended by Goldberg, (1978); patients scoring over 4 were considered to have a mood disturbance.

Results

Data from patients in stages 1 and 2 were examined using *t*-tests for independent groups. There were no significant differences for age, or anxiety and depression scores. Further analysis were therefore carried out on the combined group of 72 patients.

Table I shows the means and standard deviations of self-assessed depression and anxiety and the number above the recommended cut-off points both for the whole sample and broken down by biopsy outcome. Separate analysis of variance of SAD and SAA scores (with age and sex as covariates) were carried out with biopsy outcome as an independent variable. Biopsy outcome was a significant

factor for depression scores ($F=5.59$, d.f. 1,68; $P<0.02$), but not for anxiety scores ($F=1.64$; d.f. 1,68; NS). The covariates age and sex did not exert a significant effect. Raw score correlations of the SAD and SAA with age were not significant (confirming the results of Snaith *et al*, 1976). The analyses showed that patients with positive (malignant) outcome had higher depression scores than those with negative (non-malignant) outcome. The direction of result was the same for anxiety. Analysis of variance of GHQ scores (with age and sex as covariates) showed no relationship between mood disturbance and biopsy outcome, however ($F=0.7$, NS). GHQ raw scores showed a weak significant negative correlation with age ($r=-0.25$, $P<0.05$) and, in the 44 subjects for whom scores were available, moderately high positive correlations with SAD ($r=+0.64$, $P<0.001$) and SAA ($r=+0.47$, $P<0.001$).

The number of patients with positive biopsy scoring above the cut-off for SAD was double that of those with non-malignant outcome. Rates of SAA and GHQ mood disturbance were comparable over the two groups. In no case, however, did differences reach statistical significance.

In the procedure section of this paper it was mentioned that the two stages in which the present sample was collected were each part of larger studies. Although examination of the distribution of scores suggested that data could be pooled, nevertheless the data were collected 12–18 months apart. It was observed that the proportion of positive biopsies in the clinic changed over that interval, from 39% to 61%. The criteria for inclusion in the study did not change; eligible patients were those admitted for biopsy. However, introduction of out-patient diagnostic facilities in the interval between the two stages made it possible for patients with easily accessible tumours to be examined at their first visit to the clinic. Comparison of mean SAD and SAA scores of patients in stages 1 and 2 showed non-significant differences for those with negative biopsy outcome; however, differences were larger for those with positive outcome, and in each case scale scores were higher for patients in stage 1. One inference is that the out-patient facilities filtered out patients with easily accessible (e.g. mouth) tumours who nonetheless had substantial psychiatric distress. The higher rate of malignancies in stage 2 coupled with lower (although not significantly so) levels of mood-related symptoms is consistent with this.

Discussion

The finding that patients who are found subsequently to have buccopharyngeal tumours have higher depression scores prior to biopsy than those with negative biopsy results was not expected, and must be regarded as tentative, but it accords with some previous reports. Brown & Paraskevas (1982) reviewed the literature and suggested that depression may present as an early symptom of cancer, antedating discovery of the malignancy. This would have implications for early diagnosis and the prevention of avoidable delay in investigation. In the case of head and neck cancers, however, the effect may also

TABLE I

GHQ	17	4.2	1.9	6	35

be due to the patient's subjective appraisal of the seriousness of the physical symptom: patients with hoarseness or difficulty in swallowing attributable to a tumour may have more profound discomfort or interference with functioning than patients whose symptoms have other causes. Additionally, the non-verbal and verbal interaction of medical staff with patients (e.g. reassurance or its lack) are likely to be different even before biopsy. However, these factors do not explain why the psychological effect is more marked for depression than for anxiety. Brown & Paraskevas's preferred hypothesis is in terms of a specific immunological interference with the activity of serotonin. We have no relevant data on this, but dissociation between depression and anxiety (measured by the Leeds scales) is suggestive. No significant differences were found using a less specific measure of psychiatric disturbance (GHQ).

Maguire (1984) has drawn attention to the lack of information concerning prevalence of affective disorders in head and neck cancers. He advocates screening patients with GHQ as one strategy to increase physicians' sensitivity to the presence of mood disturbance. In the present study 48% of those with

positive biopsy fell above the GHQ cut-off, almost 40% were above the Leeds SAA (anxiety) cut-off and almost 30% were above the SAD (depression) cut-off. These findings, in conjunction with those of Morton *et al's* (1984) study of patients at a later stage in the treatment process, suggest that symptoms of depression are part of the clinical picture of head and neck cancer both early and late in its history. Clinic staff also need to be aware of the high anxiety of those undergoing diagnostic investigations for buccopharyngeal cancers, even among those patients who are subsequently found not to have a malignant neoplasm.

Acknowledgements

We should like to thank Professor P. M. Stell for providing facilities for this study and Mr J. T. Newton for computational assistance.

Editorial note

The Leeds Self-Assessment Scale has undergone further revision in order to improve suitability for assessment of mood disorder in the setting of physical illness. The revised instrument is the Hospital Anxiety and Depression Scale (Zigmond & Snaith, 1983).

Post-ECT Blood Pressure Rise and its Relationship to Cognitive and Affective Change

M. P. O'DONNELL and M. G. T. WEBB

Post-ECT blood pressure rise and its relationship to cognitive and affective change were studied in 29 depressed patients, using the Benton Visual Retention Test, the Hamilton Rating Scale for Depression, and the Leeds Self-Assessment Scale for Depression and Anxiety. No real difference was established in the Benton Test error scores before and after ECT, no correlation between rise in blood pressure and change in Benton Test error score with ECT was found, and no correlation was found between blood pressure rise and affective improvement following ECT. Previous studies which reported such correlations are not supported.

Perrin (1961), in his comprehensive review of the cardiovascular aspects of electroconvulsive therapy (ECT), noted that marked increases in systolic blood pressure (BP) immediately following ECT are the rule, whether or not muscle relaxants are used in the procedure. This elevation of BP has been associated with research into other aspects of the effects of ECT, including its effect on cognitive functioning (Hamilton *et al*, 1979; Stoker *et al* 1981). Using the Benton Visual Retention Test (BVRT) as a measure of cognitive function, Hamilton *et al*, (1979) studied 27 depressed patients before and after ECT, the second cognitive assessment being made three to four hours after the treatment. Only six patients had improved performance on the BVRT after ECT, the remainder showing impairment. It was concluded that impairment of performance on the BVRT with ECT was highly correlated with the maximum rise in systolic BP immediately following the convulsion. If this finding were confirmed, it would raise the possibility that cognitive impairment associated with ECT might be reduced or eliminated through devising means of avoiding the rise in BP (Kendell, 1981).

A further study by the same group (Stoker *et al*, 1981) re-examined these issues using an electronic sphygmomanometer. Three patterns of BP response to ECT were found, each showing different levels of cognitive performance, as measured by the BVRT four to five hours after ECT. However, in contrast to the previous study, the mean BVRT difference score for the total patient group was not significantly different from zero. Within the total group, though, an 'early rise' group was isolated with a peak BP rise occurring within one minute of shock, and with decline to near baseline levels within three minutes.

The mean Benton difference score for this group was in the direction of impairment. The two other groups isolated (a 'late rise' group with peak systolic BP reading occurring from one to three minutes after the shock, with subsequent slow recovery ($n=8$), and a 'no response' group ($n=7$), with BP rises of less than 20 mmHg) actually demonstrated improved Benton scores.

Taylor *et al* (1985) studied 20 psychiatric in-patients before and after five bilateral ECTs for major depression. Elevation of BP after ECT, using a standard sphygmomanometer, was studied using the following variables: mean peak elevation over pre-treatment levels, mean peak blood pressure during five treatments, mean percentage rise over the pre-treatment level, peak systolic BP, and peak diastolic BP. Patients showed a mean rise of 45 mmHg over pre-ECT levels; this rise was compared with any significant memory or neuropsychological changes after treatment, and also with affective change. The neuropsychological screening battery included a test of visual memory (not the BVRT). Patients were assessed before ECT and 24-48 hours after their fifth ECT. Significant deficits occurred in backward spelling (Mini Mental State Examination), verbal fluency, temporal memory, and visual memory, but none of these changes correlated with any measure of blood pressure elevation. The authors speculated, however, that the BVRT might have been more sensitive to such vascular changes after ECT.

Our study, using the BVRT, re-examined these issues. The test is one of visual memory, the performance of which requires a combination of spatial perception, short-term retention and recall and visuo-constructive abilities (Anastasi, 1968). It has

been used in several studies on post-ECT memory changes (Strain *et al*, 1968; Bidder *et al*, 1970; Hamilton *et al*, 1979; Stoker *et al*, 1981).

We also examined the suggested relationship between post-ECT rise in BP and affective change (Hamilton *et al*, 1979; Taylor *et al*, 1985). Hamilton's group speculated that the therapeutic efficacy of ECT might be associated with the rise in BP through an unknown mechanism – perhaps changes in cerebrovascular permeability. Taylor *et al* (1985), however, were unable to find any correlation between reductions in rating scores of depression and various measures of BP elevation during a course of treatment. We sought evidence of such an association, for a positive correlation between post-ECT rise in BP and reduction in depression would be an important finding to simulate new work into the mechanism of the antidepressant action of ECT.

Method

Patients were studied before and after they had received ECT, each patient being sampled on only one day. The experimental group consisted of 20 females and 9 males, with an age range of 23–70 years (mean 44.6 years). Patients were referred by their psychiatrist for treatment of unipolar depression (23 patients), bipolar depression (three patients), or depression occurring during a schizoaffective illness (3 patients). Eleven patients were studied at the time of the first ECT of their current admission; for six of these it was their first ECT ever. Seventeen patients were tested on the day of their second to eighth treatment, and one patient on her twelfth treatment. Exclusion criteria were: clinical suspicion of organic mental change, history of brain damage, neurological disease, malignancy, or recent history of epilepsy.

ECT was administered using a Mark III or Mark IV Ectron apparatus, the waveform being sinusoidal in 28 patients and brief pulse in one patient. Electrode placement was bilateral fronto-temporal in all patients. The anaesthetic used was thiopentone (200–300 mg), the muscle relaxant was suxamethonium (25–40 mg), and atropine (0.6 mg) was administered with the anaesthetic. Cognitive assess-

ment was completed in 26 patients, using the BVRT forms C and D. Assessment of affective state was carried out using the Hamilton Rating Scale for Depression (HRSD), the Leeds Self-Assessment of Depression Scale (LSADS), and the Leeds Self-Assessment of Anxiety Scale (LSAAS). Pre-treatment cognitive and mood assessments were performed on the afternoon before treatment, and post-treatment assessments made five to six hours after ECT. Systolic BP was measured by the same doctor in all cases, using a standard sphygmomanometer, before and after administration of the anaesthetic and after that of the muscle relaxant. A series of 12 readings were taken over a period of five minutes after convulsion. BP rise during ECT was taken as the difference between the post-anaesthetic level of systolic BP and the maximum level attained after the administration of ECT.

Previous studies indicated that on average, systolic BP rose, BVRT error scores increased, and mood ratings improved with ECT. For this reason the one-tailed *t*-test was used to analyse BP rises, and the one-tailed Wilcoxon Matched Pairs Signed Rank Test used for the changes in the BVRT error scores and in depression and anxiety ratings.

Results

The results showed that BP does increase on average after ECT for the total patient group, for those receiving their first ECT, and for those on their subsequent treatments (Table I). All patients showed peak rise in systolic BP within the first minute following the convulsion. However, five of our sample showed BP elevations of less than 20 mmHg, falling into the 'no response' group described by Stoker *et al* (1981).

Analysis of changes in the BVRT error scores with ECT revealed no real difference in the number of errors made before and after ECT for the total patient group or for each of the sub-groups (Table II). Analysis of changes in affective ratings showed significant improvements in affective state in all three groups of patients after ECT, although improvement was at the borderline of significance in case of the LSADS in the subsequent ECT group.

A plot of rise in systolic BP with ECT against changes in BVRT error score (Fig. 1), in HRSD scores (Fig. 2), in LSADS scores and in LSAAS scores demonstrated no significant relationships.

FIG. 2 Plot of systolic blood pressure rise (mmHg) with ECT against change in HRSD score ($n=29$).

Discussion

No difference was found in the number of errors made before and after ECT on the Benton Visual Retention Test. Furthermore, no correlation was established between rise in BP with ECT and BVRT error score change.

These findings are at variance with those of Hamilton *et al* (1979), but are in partial agreement with their study (Stoker *et al*, 1981), which failed to find a significant correlation between peak BP elevation and the BVRT difference score for the total group of patients. We note that post-ECT cognitive assessment in their first study was carried out after three to four hours, and in their second study after four to five hours, while in our study it was after five

to six hours. Ottosson's statement on the need for consistency in the time-intervals between ECT and cognitive testing may well be relevant here.

Stoker *et al* (1981) did, however, report a linear relationship between 'initial' BP rise, occurring within seconds of ECT, and the mean BVRT difference score recorded for their three patient subgroups ('early rise', 'late rise', and 'no response'). We did not find any patients corresponding to their 'late rise' subgroup, for the maximum elevation of BP invariably occurred at the first post-ECT measurement, within seconds of the treatment. We are not able to comment further, therefore, on the significance of the linear relationship between initial BP elevation and cognitive change which they identified. Five of our sample did fall into the 'no response' subgroup—a

similar proportion to that reported by Stoker *et al.* Two of our 'no response' group showed reduced error scores after ECT, but, in contrast to the Stoker *et al* findings, three patients showed increased errors. Due to the small size of this group in each study, it would be premature to draw any firm conclusions, but we cannot support the contention of Stoker *et al* that the 'no response' group show improved BVRT performance.

Our finding of lack of correlation between rise in BP and cognitive change following ECT is similar to the results of Taylor *et al* (1985), and gives a negative

answer to their question as to whether or not the BVRT might be a more sensitive test in this respect. Again, it is relevant that their methodology in relation to the timing and measurement of rise in BP and cognitive change differed from ours and from that of Hamilton's group.

Finally, no correlation was established in our study between rise in BP and changes in the Hamilton and Leeds affective ratings after ECT. These findings are in agreement with Taylor *et al* (1985), and do not support Hamilton's speculation about such an association (Hamilton *et al*, 1979).

(Accepted 18 September 1985)

Is There a Lithium Withdrawal Syndrome?

A. J. MANDER

Patients who discontinued lithium after a mean of 29 ± 21 months prophylaxis were compared with a similar group who were not taking the drug; all had only been in hospital once, and satisfied DSM-III criteria for mania. During the first three months following withdrawal of lithium, significantly more patients relapsed than in the control group; after this period, the rate was identical. These findings suggest that lithium withdrawal exists as a clinical phenomenon and that a period of lithium treatment does not improve the long-term prognosis, once the drug has been stopped.

Discontinuation studies in the early 1970s were concerned with proving the efficacy of lithium as prophylactic medication, and consequently did not look closely at the possibility of relapse being caused by drug withdrawal. Little attention was paid to the temporal relationship between discontinuation and relapse. It was generally assumed that the pattern of relapse reflected a recrudescence of the natural history of the disease process in a unprotected individual, rather than a drug-induced state. Early relapses were noted in some studies (Melia, 1970), but did not occur in sufficient numbers to arouse comment (Grof *et al*, 1970; Baastrup *et al*, 1970). One of the foremost authorities on lithium therapy has stated that he has never observed withdrawal phenomena or rebound illnesses (Schou, 1980). However, if there is a genuine withdrawal phenomenon it would have important implications both for the method used to discontinue patients from their treatment and also for the management of a rapidly recurring episode after stopping lithium.

Lapierre *et al* (1980) reported 20 cases who had their lithium withdrawn on an open basis, for five days; four patients relapsed within this time and required admission to hospital for mania. This report seems to provide some convincing evidence of a rebound phenomenon, although it has to be interpreted with caution: three of the relapsed patients had experienced a mean of two affective episodes per year in the period between first contact with psychiatric services and the prescription of lithium. Their rapid relapses could therefore be a function of their severe illnesses, rather than a result of lithium withdrawal.

Klein *et al* (1981) switched 21 patients to placebo, but it is not clear whether this was under single-blind conditions; the diagnosis was of affective illness, but no criteria for this are stated. Although 11 patients

were reported to have "relapsed into severe psychotic states with paranoid, manic and depressive symptoms within 14 days", it does not appear that any of these were severe enough to warrant admission. All subjects restarted lithium after five weeks.

Christodolou & Lykouras (1982) studied 18 patients (17 of them bipolar) and reported that three relapsed within four days of double-blind placebo substitution. Two of these relapses were reported as severe and one required ECT, but the severity of symptoms was assessed by rating scales, and none of the patients required admission. Among the assessments made on these patients was a scale measuring side-effects such as anxiety, tremor, restlessness, fatigue, irritability, and other symptoms normally associated with a drug withdrawal state. No increase in these was noted.

King & Hullin (1983) described four patients who suffered minor symptoms of heightened anxiety, irritability, and emotional lability as a result of lithium withdrawal; none of the patients had affective relapses, and none required admission to hospital. Withdrawal symptoms were then studied retrospectively by questionnaire, but usable replies were obtained from only 18% of the patients approached, and such a biased sample means that little reliance can be placed on their stated results.

Sashidharan & McGuire (1983), in a carefully conducted retrospective study of 22 patients satisfying Feighner criteria for primary affective disorder, could find no evidence of a rebound phenomenon: only two patients relapsed during the first two months after discontinuation. In all, 15 patients relapsed, the majority staying well for over one year, and they concluded that there was 'a gradual pattern of relapse over a period of months following discontinuation'.

Method

The study group was drawn from patients admitted for the first time between 1 January 1970 and 31 December 1981; all satisfied DSM-III criteria for mania (American Psychiatric Association, 1980). Patients with puerperal illness or concurrent organic brain disease, or who were not resident in the UK at the time of their attack, were excluded. Two patients were excluded who committed suicide – one during a first admission and the other on the day of discharge. Also excluded were patients who did not have a clear gap between the stopping of their lithium and the onset of symptoms, as recorded in their case notes.

To be included in the study, patients in both the experimental and control groups had to remain well for at least three months following discharge, to ensure that any subsequent readmission was for a genuine relapse, as opposed to a recurrence of symptoms from the original episode. This excluded a similar number of patients from each group (29% of those on lithium and 22% of those that were not, $\chi^2 = 0.52$, d.f. = 1, NS). The control group therefore consisted of 50 patients, 42 of whom had never been on lithium, and eight who had only taken it for a period of less than three months; the experimental group consisted of 29 patients, established on prophylactic lithium for at least three months following discharge. Any patient who had three successive serum lithium estimations during follow-up of less than 0.4 mmol/litre was to be excluded from the study, but none were found. The patients subsequently took lithium for a mean of 29 ± 21 months.

From the admission notes and nursing records, demographic and clinical factors were recorded including age, sex, previous number of affective episodes requiring treatment but not admission, duration of admission, and family history of affective disorder. The severity of illness was estimated by the Modified Manic Rating Scale (MMRS) (Blackburn, 1977), which was further modified so that it could be used retrospectively on the admission notes. Inter-rater reliability with a rater blind to the purpose of the study gave a correlation of $r = +0.71$, which is in good agreement with the value quoted by Blackburn for the interview situation ($r = +0.68$ to $+0.79$). All patients and their GPs were contacted to provide a full follow-up picture until the close of the study (31 December 1983). The follow-up thus ranged from 2 to 14 years.

The outcome of the two groups was assessed by the life table method, which is the method of choice for analysing longitudinal data (Fleiss *et al.*, 1976). Relapses during the course of manic-depressive illness have been shown to be exponential (Grof *et al.*, 1970; Schou *et al.*, 1970), and when plotted on a semi-logarithmic scale give a straight line, the slope of which is the 'decay constant'. Data from all patients in the study were used. A common starting point (time 0) was defined; at this point, formal follow-up began. For the control group, time 0 was three months after discharge from hospital, when they were considered to have recovered from their first illness. At this point, the experimental group had been established on lithium for three months; time 0 for this group was the point at which they subsequently discontinued their medication. Successive probabilities of remaining well over three month intervals from these points were

calculated for both groups, relapse being defined as readmission to hospital.

Accurate information regarding the date of discontinuation of lithium was essential. Out of the 17 cases that were readmitted, seven had discontinued their drug in consultation with the medical staff, and this was clearly recorded; they subsequently developed symptoms and were readmitted. In another five cases, it was recorded at the time of their readmission that they had stopped their lithium, and developed symptoms 5, 7, 9, 14 and 21 days later (in two of these cases the dates of stopping lithium and the subsequent re-emergence of symptoms were corroborated by the patients' wives). In a further two cases, information regarding discontinuation and subsequent readmission were supplied by other hospitals. Finally, in three cases, it was recorded that the patients stopped their lithium and then developed symptoms, but the exact date of discontinuation was not clear. In these cases the date of the last serum lithium determination was used, as supplied by the lithium office, which records the lithium levels of all patients in the region. These patients were readmitted two months, one year and four years later. This method is unlikely to have introduced any error into the results, since only one patient was involved in the period of significant difference between the groups. Since the analysis of outcome after discontinuation was calculated in three month periods, this patient would, in any event, appear in this first period.

Any retrospective study is dependent on the quality of the case records. This study was greatly facilitated because in Edinburgh all notes are typed before inclusion in the file, and all first admissions have a full and detailed case summary, prepared after discharge.

Results

Although patients were not randomly allocated to experimental or control groups, they did not differ on any factors that have been proposed as predictive of outcome. Thus, mean age was 34 ± 13.5 years (control 37 ± 14.2 years), number of patients with previous episodes was eight (control seven, $\chi^2 = 2.2$, d.f. = 1, NS), family history of affective disorder 11 (control 12, $\chi^2 = 1.9$, d.f. = 1, NS). Length of hospital admission did not differ: 7.1 ± 3.5 weeks (control 5.7 ± 3.5 weeks, $t = 1.67$, d.f. = 77, NS). The diagnostic breakdown of the relapses in the two groups was similar: of the experimental group, 13 (76%) were manic, compared

FIG. 1 Semi-logarithmic plot for discontinued lithium ($n = 29$) and control ($n = 50$) groups. Slopes were significantly different over the first 3 months ($P < 0.05$).

22-24	29	2	0.07	0.93	0.54

with 17 (68%) of the controls. The only criterion on which they did differ was severity of initial illness as rated by the MMRS (experimental group 28.0 ± 7 ; control group 22.4 ± 8 ; $t=2.67$, d.f.=76, $P<0.01$). All chi-squared analyses included Yates' correction factor for continuity; t -tests were 2-tailed for independent samples.

The life tables (Tables I and II, Fig. 1) show that there is an increased risk of relapse over the first three months following the discontinuation of lithium, compared with the first three months for the control group after recovery from their initial illness ($z=2.17$, $P<0.05$). After this period, the decay constants (rates of relapse) for the two groups are identical.

Discussion

This is the first study to report on a group of bipolar I patients after a first illness, with a similar group as a control. Readmission rather than the recurrence of symptoms was chosen as the outcome measure, since it is much more accurate in a retrospective study.

The increased risk of relapse over the first three months following the discontinuation of lithium lends support to the hypothesis that a withdrawal state does exist. As documented above, symptoms tended to recur rapidly, most patients being readmitted within this first follow-up period. It is not possible retrospectively to be certain that the patients were well at the time they stopped their lithium, although great care was taken to exclude any patients where there was any doubt. Independent confirmation of lack of symptoms was obtained for five out of the eight patients that relapsed during this first period (three from medical staff, two from spouses).

The slopes of the graphs after the first three months are identical, indicating that a period of lithium treatment (in this case, a mean of $2\frac{1}{2}$ years) does not improve the prognosis once it has been stopped. There is therefore no justification for short periods of prophylaxis.

Patients were not randomly allocated to treatment

or no-treatment, but differed only on the severity of their initial illness, as rated by the MMRS. This is not surprising, since it is reasonable to assume that patients were put on lithium after their first admission because the clinicians believed (for whatever reason) that they were at an increased risk of future relapse. An alternative explanation for the results then seems possible, but if this group had an increased risk of relapse as a result of having had a more severe initial illness, a straight-line decay graph of a steeper slope than the control group would be expected. This is not the case, however, and no other studies have shown severity of symptoms to be predictive of future prognosis.

The results of this study are in contrast to that of Sashidharan & McGuire (1983), which is the only other one of comparable size. However, the latter shows important differences, with a mix of unipolar and bipolar patients, and it is not clear whether the bipolar patients are I or II; in the present study all patients were bipolar I, and it may be this group that is at high risk of a rebound state developing. This difference might go some way towards explaining the contradictory findings in the literature. Such a possibility is further supported by the fact that seven of the eight relapses in this study in the first three months were for mania (the other being for a mixed affective state), whereas in the earlier study there were an equal number of manic and depressive relapses.

Comparison with the study of Bastrup *et al* (1970) is also interesting: although he states that "there was no indication of rebound or abstinence

effects", the investigation was completed in five months. During that time, 12 out of 22 manic depressive patients who had been switched to placebo relapsed; these also were equally divided between mania and depression, which might be a reflection of the ratio of bipolar to unipolar and bipolar I to bipolar II patients in the study. Although it is stated that "the relapses were spread over this period in a manner subjected to analysis elsewhere", these data are apparently unpublished, and no further conclusions can be drawn about them.

The possibility of a lithium withdrawal state has obvious implications for clinical practice. Early relapses might, in the absence of the phenomenon being recognised, lead to the patient being persuaded to restart lithium, and then to take it for a much longer period than necessary, perhaps for life. However, had the relapse been treated without lithium, the future prognosis might have been good and further prophylaxis unnecessary.

This is a retrospective study, and its data suggest that a prospective double-blind discontinuation study is needed of bipolar I patients, concentrating particularly on the temporal relationship between stopping the drug and the recurrence of symptoms. If the increased risk of relapse during the initial withdrawal period is confirmed, identification of types of individuals prone to this type of reaction would be helpful.

Sodium Bicarbonate Abuse: A Case Report

Sodium bicarbonate abuse is unusual, and rarely reported. A patient was extensively investigated at several hospitals for a recurrent hypokalaemic metabolic alkalosis; it transpired that she had been abusing sodium bicarbonate for 8 years and had gained hospital admission at will by taking large amounts. She also showed features of the Munchausen syndrome.

Case report

In 1980, a 21 year-old hospital secretary was admitted to hospital for investigation of a five year history of intermittent vomiting, weight loss, and episodes of light-headedness, nausea, headache, and tingling around the mouth. She denied overbreathing. Clinical examination was normal, apart from a positive Chvostek's sign; blood pressure was 90/60 mm Hg. Investigations showed a plasma bicarbonate greater than 40 mmol/l (normal range 20-30 mmol/l) and a low plasma potassium at 1.8 mmol/l (normal range 3.4-5.3 mmol/l).

Her hypokalaemic metabolic alkalosis was investigated by a barium meal and follow-through, upper alimentary endoscopy and duodenal biopsy, sigmoidoscopy and rectal biopsy, all of which were normal. Liver and thyroid function tests, and cortisol and Synacthen tests were also normal. The electrocardiogram showed a sinus rhythm with T wave flattening, compatible with hypokalaemia.

No cause for her symptoms was found, and she was prescribed eight effervescent potassium tablets daily (53 mmol K⁺/day) and discharged. She moved to the Midlands, and over the next two years was admitted on five occasions with recurrent hypokalaemic alkalosis, despite out-patient treatment with potassium supplements. Her plasma potassium levels on admission ranged from 1.8-2.2 mmol/l, with plasma bicarbonate levels greater than 40 mmol/l. Blood gas analysis showed a raised pH and raised pCO₂. She complained of diarrhoea, nausea, generalised weakness, palpitations, muscle cramps, and occasional slurred speech. Plasma renin and aldosterone, intravenous pyelography, and urine acidification tests were all normal; one urinary acidification specimen was found to contain orange squash. Urine tests showed she was excreting 120 mmol of sodium and 120 mmol of potassium daily. Her creatinine clearance was 90 ml/min. In view of the recurrent hypokalaemia, Bartter's syndrome and pseudo-Bartter's syndrome were considered (Robb *et al*, 1984). The evidence for Bartter's syndrome was inconclusive, however, and she persistently denied diuretic or laxative abuse. In 1982 she moved to another area, and was admitted to hospital complaining that she had become rapidly tanned on minimal exposure to the sun; computerised tomography scanning of the adrenal glands showed no abnormality.

In 1982 she moved to Devon, and was admitted for further investigation of her recurrent metabolic disturbance. Sucrose was found in her 24-hour urine collection. A psychiatric opinion was requested, and it was during this interview that she admitted to sodium bicarbonate abuse over the previous eight years. She had started taking it to

relieve nausea, but found that large amounts gave her a 'buzz' - a feeling of well-being and alleviation of tension. Her consumption increased to daily amounts ranging from 50-150 g, and attempts at withdrawal produced craving and misery. Furthermore, she realised from her first episode of in-patient investigation that she could gain urgent admission to hospital by deliberately increasing her bicarbonate intake; she was able to avoid stressful events by this means and also to gain medical attention.

Two attempts at in-patient withdrawal were followed by a return to dependency. Over the past 12 months she has had regular out-patient supportive psychotherapy. She has now developed slow hesitant dysphonic speech, with periods of mutism, and displays intermittent pseudo-athetoid movements of her arms: these signs are only present at interview.

Discussion

The pathogenesis of a metabolic alkalosis was well described by Seldin & Rector (1972). The common causes are: vomiting, diarrhoea, laxative abuse, relief of chronic hypercapnia, Cushing's syndrome, primary aldosteronism, Bartter's syndrome, and adrenal steroid therapy.

Recent reports have described a metabolic alkalosis secondary to the topical application of 9-alpha fludroprednisolone (Pachon Diaz *et al*, 1983), following the abuse of a nasal spray (Pepe *et al*, 1983), and with fludrocortisone therapy (Burns *et al*, 1983). A case of sherbet fountain (sodium bicarbonate) addiction presenting as hypokalaemic alkalosis was described by Kaye & Williams (1983). Chronic metabolic alkalosis is frequently accompanied by potassium depletion, due to distal tubular potassium secretion uninhibited by competition for secretion with hydrogen ions, and is associated with a high intracellular potassium concentration. Administration of sodium bicarbonate in doses up to 140 g/d for periods of up to three weeks has been shown to produce a metabolic alkalosis with no injurious renal sequelae (Van Goidsenhoven *et al*, 1954).

Our patient proved a challenging diagnostic problem. For three years, she willingly submitted herself to numerous unpleasant and potentially hazardous investigations, without the real cause of her recurrent metabolic disturbance being detected. She was able

to precipitate urgent hospital admission at will, and spent many weeks at different hospitals undergoing expensive investigations and enjoying medical attention. She exhibited many features of the Munchausen syndrome, and had some medical knowledge through her work as a hospital secretary, with easy access to hospital libraries and medical journals

(O'Shea *et al*, 1984). She varied her symptoms and mode of presentation subtly to ensure that further investigations would be carried out.

Despite regular supportive psychotherapy, behaviour therapy, and treatment with antidepressants and benzodiazepines, she continues to abuse sodium bicarbonate.

Koro in an Israeli Male

The Koro syndrome, a 'special cultural psychiatric syndrome', is encountered in South China, Malaysia and Indonesia, especially among people of Chinese origin. There are only eight case reports of Koro from the Western hemisphere. We present a typical primary Koro patient from Israel. Jewish cultural mores are a possible contributory factor.

Koro is a syndrome of acute anxiety accompanied by a conviction that there is penile shrinkage and dissolution (Yap, 1965), and by a fear of death. It is considered a special culture-bound psychogenic syndrome, as it is strongly influenced by beliefs of the Yang (male) and Yin (female) humours activity in human beings - principles elucidated first by Chu Chen Hang some 700 years ago (Lee *et al*, 1962). This syndrome has been considered variously as an obsessive-compulsive illness, anxiety neurosis, acute

castration fear, psychotic-like syndrome, depersonalisation syndrome, and hysteria (Yap, 1965; Gwee, 1963, 1968; Kobler, 1948; Marks & Lader, 1973; Rin, 1965), based on patients from the area to which the syndrome is endemic: South China, Malaysia and Indonesia.

In addition to the report of Baasher (1963), who stated that Koro is encountered in Sudanese people, there are only eight Western case reports (Dow & Silver, 1973; Lapierre, 1972; Bychowsky, 1952; Yap,

1965; Edwards, 1970; Barret, 1978; Hes & Nassi, 1977); except for one, these are secondary to organic brain syndromes or major psychiatric disorders such as depressive illness and schizophrenia. Two of the eight case reports mentioned are from Israel (Hes & Nassi, 1977), including the one primary case. Unfortunately, due to language difficulties there is no detailed intrapsychic description of this patient, except for his symptomatology.

Yap (1965) differentiated the syndrome as mainly a depersonalisation state rather than a pure hallucination, in the sense that it is not influenced by affective arousal; however, the patient's insight into the symptom is restricted, unlike that of most depersonalised patients. The insight defect was regarded as a consequence of cultural background and the social norms of beliefs. We present an Israeli Jewish Koro patient whose disorder is primary and who has the same insight restriction, as a result of neurotic intrapsychic structure.

Case Report

A 56 year-old man, married and the father of three children, was admitted to the Geha Psychiatric Hospital because of acute anxiety attacks, consisting of a feeling of penile dissolution and shrinkage, which had started three years before.

Born to a Jewish family in Iraq, the patient was the second son of eight children, his father was a merchant, and the family's economic situation was good. He studied for ten years, and up to his immigration to Israel at the age of 22 he worked as an assistant accountant. He served his full term as a soldier for two years in the Israel Defence Forces, and in later years continued to fulfill his civilian obligations through reserve duty. For the past 25 years, he had worked as a printer. Up to his marriage at the age of 32 he proclaimed himself to be a 'ladies' man', and enjoyed going out with friends.

He married his second cousin, under pressure from his parents. The couple could not afford to buy a flat of their own, and were provided with a place within his parents' house. The patient described himself as happily married, a devoted and a loving family caregiver, "hypersexual", and with a very satisfying marital sexual life.

Some years before his admission the patient's wife started to pressure him to obtain a flat of their own, complaining mainly of lack of privacy. Later on, she developed a delusion of being loved by her previous boss at work, and avoided sexual engagement with her husband in order "not to betray her lover". The wife was finally admitted to hospital for two months, and a diagnosis of schizophrenia was made, after she returned home she showed less sexual drive, and the patient started practising masturbation.

In order to earn more money, to enable him to move from his parents' house, he started to work extra night shifts. The patient claimed that his troubles started after being frightened by a black cat in the dark during one of these

nights. A few days later, pain and a feeling of penile dissolution appeared. In an attempt to avoid shrinkage of the penis, he used to pull it by hand. He did not stop working, but used to sit in a twisted position, with one of his hands holding his penis most of the time.

At times he felt intense pain in his groin, and felt compelled to show his wife or workmates his "contracting penis". He seldom had sexual relations with his wife, and complained about increasing pain following intercourse. He eagerly sought the help of urologists and was intensively checked, but no physical pathology was found – which did not offer the desired relief. He believed that he had a fatal disease. A few months prior to his admission, the patient was dismissed from his job. His new job included lifting up objects, but he claimed that he could not bend, because that sort of movement caused further retraction of his already "shrunk" penis. Gradually social disability took over, as he refrained from going to work to avoid the appearance of the symptoms in public.

Three years after his initial complaint, he was referred to the psychiatric ward. During his mental status examination the patient was seated with his whole body turned to one side, in order "not to sustain pressure on his penis". Most of the time his hands were holding his groin. He gave very detailed information about his illness, and showed marked anxiety and fear concerning his "disappearing penis". He also complained of sleep difficulties and of general weakness. Orientation and memory were intact. There was no evidence of auditory or visual perceptual disturbances, and there were no other depressive or psychotic symptoms.

An underlying depressive state was suspected, and a course of clomipramine (up to 200 mg/day) was given for 40 days, but without clinical improvement. Treatment with phenelzine (up to 45 mg/day) was stopped after three weeks, as the patient developed dizziness, marked anxiety, and psychomotor agitation. A therapeutic trial with chlorprothixene also failed to affect the chief complaints. Minor tranquilisers (oxazepam) moderately reduced the frequency of the anxiety attacks.

The patient explained his anxiety as a consequence of a feeling of penile disappearance and pubic "emptiness". The dissolution of the penis symbolised for him his loss of virility. He had a rigid self-image of masculinity versus femininity – the image of a strong man caring for his weak wife, proving his virility through frequent sexual activity. His self-description of masculine omnipotence was completely contrary to results of psychodiagnostic tests (Rorschach, Thematic Apperception Test, Wechsler Adult Intelligence Test, and Bender); he was found to have very low masculine self-esteem, perceiving women as big and threatening.

The patient was also found to have strong sexual drives, accompanied by aggressive impulses toward the sexual object. These drives evoked severe anxiety controlled by obsessive-compulsive mechanisms.

In psychotherapeutic sessions the patient described a poor family situation, in which his wife started to reject his needs for sexual performance. He felt very hurt, increased his masturbatory habits, and believed he consequently became ill, he saw masturbation as the main reason for his illness, as it "weakens the penis and the body, and causes

loss of sperm". He repressed and denied any connection between the strained relations with his wife and the illness. In addition, he received secondary gain by escaping into illness when there were hard times in his work as a printer, and the danger of losing his job became a reality. He continued to show his penis frequently during attacks of anxiety to his room-mate or the therapist, as he had done before with his wife and workmates.

Discussion

Koro is considered a culture-bound psychogenic syndrome (Lkeinman & Lin, 1981; Robert, 1982). Our patient suffered from a syndrome identical to the Koro syndrome described in the literature. He was Jewish, born in Baghdad, and had no knowledge of Far Eastern cultural beliefs. However, in Jewish tradition there is a prohibition against masturbatory acts, which it is claimed can cause physical problems, although there is no special reference to shrinkage of the penis.

Jewish laws and traditions put great emphasis on the continuation of the family line; within that context lay the prohibition of spilling the seed (including masturbation). Underscoring that attitude is the practice of levirate marriage (Deuteronomy 22, 3-6). According to that custom, if a husband died without heirs his closest male relative was compelled to take the widow as a bride and provide her with children. The Bible tells the story of Onan who, after his brother's death, refused to fulfill his duty and decided "when he went into his brother's wife, that he would spill on the ground lest he should give seed for his brother" (Genesis 38, 8-10). Though scholars still debate whether Onan was practicing masturbation or coitus interruptus, his 'sin' cost him his life, and his name is the source of the Hebrew word for masturbation, *onanut*.

The great Jewish philosopher and physician Moses

Maimonides (1135-1204) is reported by Hess & Nassi (1977) to have said that "to spill the semen is to spill the power of the body and its life and the light of the eyes. The more one spills the more the body's power and life diminish". Our patient's complaints were much in the same vein. He felt the dissolution of the penis with anxiety and had a very restricted insight into the symptom.

Psychotherapy and psychological tests revealed a neurotic constellation over conflicts of sexual identity, castration fears, and loss of control over severe sexual aggressive impulses. The 'dissolution' of the penis appeared to serve a neurotic purpose by letting the patient obsessively deal with his penis without using it in reality, in addition to the obvious secondary gains.

The patient was immature, much like patients from Hong Kong described by Yap (1965); Yap saw it as a depersonalisation syndrome, created by dissociative mechanisms affecting the integrity of the body image. Our patient's poor insight into the symptom was affected by intrapsychic defence mechanisms of denial, repression, and dissociation, and not by cultural beliefs as in classical Koro patients.

The precipitating psychological factors—guilt over masturbation and sexual rejection by his wife—are also often described in the literature of classical Koro patients, but here it could be rarely attributed to the cultural prohibition of onanism, so deeply embedded in the Jewish tradition. The appearance of Koro in an otherwise 'normal' people in the Far East is attributed to cultural beliefs, which may be the cause of the relatively high incidence there. However, appearance of a primary Koro syndrome in other parts of the world is possible: the fact that there have been few case reports up to now may be due to either a genuinely low incidence, or to Western codes of classification.

Anorexia Nervosa in a Woman Totally Blind Since the Age of Two

A 28 year-old woman, blind since the age of two, had become anorexic at 21. She had eating problems as a child, and weight preoccupation from her teens onwards. Psychiatric admission with other anorexic patients preceded the illness. Inability to see oneself does not protect against anorexia nervosa.

Body image disturbance is one of the hallmarks of anorexia nervosa (AN). Of all the psychiatric syndromes, AN is most closely linked to disturbance in the visual body image. When one thinks of being too fat or too thin, the instantaneous image conjured up is a visual one. Therefore, development of AN in a patient who was blind from an early age not only presents an unusual coincidence of medical problems, but also raises interesting theoretical issues.

Case report

A 27 year-old blind woman was referred for evaluation of possible AN; although in the past she had bradycardia, with a pulse as low as 40, there were no current major medical problems. At the time of evaluation she was 5'2" in height and weighed 44.5 kg—78% of the recommended average weight (RAW) for her height according to the 1983 Metropolitan Life Insurance Company tables. The preceding year she had intentionally lost weight from 44.6 kg (82% RAW) down to 43.9 kg (69% RAW), and at that point became and subsequently remained amenorrhoeic. At 44.5 kg she felt far too fat, and was so terrified and depressed by her weight gain that she frequently felt suicidal. She did two or three hours per day of aerobic exercises, depending on her weight;

she also bought a computerised talking scale that called out her weight, and weighed herself several times a day. (Not only does this scale talk, but it also has a memory, permitting it to say such things as "You've gained a pound since the last time you weighed yourself".) Although she tried vomiting a few times, she found it painful and repulsive. However, she used two types of diuretic tablets, many over-the-counter diet pills, and one or more enemas on a daily basis for at least two years. Her daily caloric intake was estimated to be between 200-600 calories—primarily in the form of vegetables. There were no episodes of bulimia.

She was born, the youngest of three daughters, into a troubled marriage; both parents were intermittently alcoholic, and her mother had been very thin in the past. At the age of 18 months she developed a retinoblastoma in one eye, which was treated by enucleation, and received radiation therapy to the other eye; by the age of two, all residual eyesight in the remaining eye was also lost. She recalls being tied down for the radiation treatment, and developed a fear of being restrained.

From a very early age, her parents always wanted her to eat more; at times she would claim not to like certain foods, even if she did, because she didn't like being forced to eat. She recalls having developed strong aversions to many foods, simply on the basis of not liking the sounds of their names, even if she enjoyed the tastes. For example, the words pizza, crust, and spinach were ugly to her, so she

would never eat those foods. Also, gelatin deserts 'wiggled', so she would not eat them. She rarely tried new foods after the age of six. She remembers people commenting about her weight being too low.

When she was six her parents, always fighting, divorced for the first time they remarried when she was ten, constantly battled, and divorced a second time when she was 20. As a child and through her teens she worshipped her father, but subsequently came to realise that he had always been hyper-critical of both her and her mother. She also learned that her father had been unfaithful to her mother, and developed the idea that "men cheat and try to control you".

Early adolescence was difficult, and for the first time in her life she felt tremendously unhappy. She attended normal schools that had only a few special programmes for the blind. When she was 13, children in school were unpleasant to her, teased her often, and went so far as to steal her cane. At 13 she began to menstruate and develop physically, and became horrified by the idea that she might start to get fat. She said "bikinis were in then, but I would never put on a bathing suit because my body was changing and I was starting to feel fat like a whale". Her first periods frightened her very much, and subsequently she has welcomed the amenorrhea resulting from her weight loss as a boon. All through high school she had poor self-esteem, a great deal of self-hatred, and felt alone and ostracised much of the time.

At the age of 18 she left her family, and went away to college in another state. She had a guide-dog during her first year. She did well, and hoped to have a musical career. At the end of that year many of her friends left, and she transferred to a good music course at a small university near the family's home. She remained there for 18 months, after which for obscure reasons she was abruptly discharged; her family was told that because of her blindness, the teachers didn't know quite how to handle her, and the university refused to provide any further explanation. This expulsion shattered her already fragile self-esteem and she suffered her "nervous breakdown": she became severely depressed, paranoid, withdrawn, and suicidal, and began to slash herself. Having lost her sense of direction and meaning in life, she was diagnosed as having a mixed personality disorder and a secondary depression.

She was admitted to a private psychiatric hospital, where she remained for the next 18 months. She cut her wrists deeply enough to require sutures many times, and developed the idea that the wounds needed to stay open or else she would be a bad person. At this hospital she first encountered women with AN, and initially thought they were "very weird". During this period the idea that she needed to lose weight first took hold; the most she had ever weighed was 50 kg (88% of RAW), and her usual weight had been 47.7 kg. While in hospital she dieted down to 43.9 kg, and felt that she was 'bad' when her weight increased. After 18 months, still at a low weight, she was discharged to a long-term care facility, but within a few days threatened suicide with a loaded gun and was readmitted. Over the next four years she had five additional admissions for impulsive suicidal behaviour.

She began to experience herself as fat through tactile

exploration of her arms and her legs, but her perceptions of her limbs were inconstant: "sometimes they felt thin, and sometimes they didn't, changing sometimes from minute to minute or hour to hour". She was aware that some of the changes were actually related to fluid shifts rather than fat. But, she said, "anything that is weight I don't like. When I feel fat I get depressed and suicidal." During this period she was chronically depressed, and was given the DSM-III diagnosis of atypical depression (American Psychiatric Association, 1980). She made additional multiple suicide gestures and was treated, to no avail, with a variety of antidepressants, including imipramine, amitriptyline, tranylcypromine, phenelzine, and lithium to which triiodothyronine was added. She also had a course of 12 ECTs, which had little effect.

During periods out of the hospital she lived sometimes with her sisters and sometimes with her father; he was very critical of her, and they even had physical fights. She visited her mother (who moved away from the area) only intermittently.

She received out-patient psychotherapy, where DSM-III dysthymic disorder was diagnosed, in addition to her other diagnoses. Ultimately, with this help, she managed to move away from her father to share an apartment with a platonic male friend she had known for several years. In that setting her weight rose, to her horror, to the 44.5 kg she weighed at the time of evaluation.

Family history

Her paternal grandfather committed suicide, and a maternal uncle died of alcoholic cirrhosis. Her oldest sister has episodes of binge eating, is always overweight, and is always on a diet. Her middle sister, a runaway who had once been addicted to drugs, had settled down, and was currently married and doing well.

Mental state

On examination, she was a thin, pleasant woman who spoke easily and openly about her history and mental life. She talked about her past suicidal behaviour and current death fantasies, alternating between blandness and a wry, wistful smile. At times she giggled with mild anxiety, but was otherwise composed and appropriate. She described having had trouble throughout her life in making decisions and in dealing with new situations, particularly social situations, which she found anxiety-provoking. There was no evidence of hallucinations, and the only evident fixed preoccupations were those concerning weight and food.

Her calm appearance during this evaluation was quite different from her mental state as previously recorded in her medical records, in many of which she had been described as depressed, distraught, histrionic, and desperate.

On the Eating Disturbance Inventory (Garner *et al.*, 1983) scores on all eight sub-scales were at or above those reported for patients with AN. Here, too, she demonstrated exaggerated responses to the various sub-scales. Since this measure is not yet widely known, we present her most salient scores, followed by the AN and female comparison

(FC) group averages published by Garner *et al* (or, where pertinent, the restrictor or bulimic sub-groups referred to as ANR or ANB): drive for thinness 21 (AN=15.4; FC=5.0); bulimia 1 (ANR=2.7; ANB=10.8; FC=2.0); body dissatisfaction 21 (ANR=14.2, ANB=17.4, FC=10.2).

Discussion

To the recent proliferation of unusual cases of AN (Buchan & Gregory, 1984), we add what is to our knowledge the first published case of its development in a woman blind since the age of two. In our view the diagnosis is valid, based as it is on the presence of all the major psychological, behavioural, and physical manifestations of AN. That these were preceded and accompanied by other psychiatric difficulties, most notably personality disturbances, does not diminish the accuracy of this diagnosis. The patient's exaggerated responses on the Eating Disturbance Inventory were consistent with her observed behaviour in the home and with the meticulous records she kept regarding her intake. Her fussiness with food, use of food in control struggles with her parents during childhood, and weight preoccupation during early adolescence all provided a background of vulnerability. Her subsequent AN coalesced during a time when she was without a sense of direction or purpose – when her sense of self, always shaky at best, was lowest since she was no longer a musician or university student; AN then provided her with an identity, at a time when she desperately needed one. Although she remained volatile and self-destructive during the 18 months following the development of the AN, it was her view and that of her therapists that the severity of her self-destructive slashing diminished as her AN deepened; it seemed as if, to some extent, she traded the former for the latter. The fact that she modelled herself after patients with AN that she met on the ward is consistent with her shaky sense of self.

The perfectionistic strivings she had as a student and musician, the presence of binge eating episodes in one sister, and the harsh, critical nature of her father are all possible contributing factors. This patient also exhibits many masochistic features, common in patients with AN (Hogan, 1983). From a

psychodynamic point of view, she clearly incorporated the harsh, critical, and unforgiving aspects of her father, and brutalised herself with self-destructive slashing, starving, and unrelenting intrapunitive criticism.

The fact that she was sighted during her early infancy might have contributed to a more accurate self-and-other representation than that usually expected in congenitally blind children, but hers is still seriously impaired. The trauma of the enucleation and of the restraint required for radiotherapy might have deeply influenced her personality development. Conceivably, the radiotherapy might have affected the development of nearby areas of her brain, and thus contributed to her subsequent psychiatric difficulties.

The development of body image in blind children appears to be impaired, relative to sighted children. Given the importance of visual communication between mother and infant in the development of a good relationship between the two and in the development of the infant's sense of self (Robson, 1967), it is remarkable that the personality development of blind children is ordinarily so normal (Freiberg, 1977). This may be due to the great amount of redundancy in the mother-child communications system and in the intrinsic autonomous development of personality. Kinsbourne & Lempert (1980) found that congenitally blind children do internalise a representation of the human body, but compared with that of sighted children it is impoverished and systematically distorted – a defective representation. The other senses permit a spatial representation of the body, but one that is inaccurate. Freiberg (1977) found the development of the sense of self or 'I-ness' to be delayed. In this regard, it would be of interest to know if cases of AN have ever occurred among congenitally blind children, and to assess the extent to which preoccupations with weight and appearance occur in such populations.

It is clear from this case that the absence of sight from an early age and of all the attendant visual information regarding the shape of one's own body relative to that of others does not preclude the development of AN. You do not have to see yourself to want to be thinner.

Identical Twins Discordant for Presenile Dementia of the Alzheimer Type

In genetically proven identical female twins, discordant for presenile dementia of the Alzheimer type, the affected twin began to dement at the age of 49, and died 15 years later; the diagnosis was confirmed at post-mortem. The surviving twin remains clinically unaffected 20 years after the onset of dementia in her sister. Environmental aetiological factors are postulated to account for this discordance.

Alzheimer's disease (AD), the major cause of dementia, is arbitrarily divided into presenile dementia of the Alzheimer type (PDAT) and senile dementia of the Alzheimer type (SDAT), depending on whether the illness starts before or after the age of 65. Although previous evidence (Newton, 1948; Lauter & Meyer, 1968; Constantinidis, 1978) implied that these forms of AD are essentially identical disorders, differing only in age at onset, recent neuropathological (Bondareff *et al*, 1982) and neurochemical (Rossor *et al*, 1984) findings suggest a nosological distinction between the two.

AD may result a variety of different aetiological factors. Relatives of probands have an increased risk of dementia in later life (Sjogren *et al*, 1952; Larsson *et al*, 1963; Constantinidis, 1978; Heston *et al*, 1981), but the mode of transmission is uncertain. The results of most pedigree studies are compatible with polygenic inheritance, but some families AD appears to be inherited as an autosomal dominant disorder (Breitner & Folstein, 1984).

The study of biological markers such as hapto-globin types (Stam & Op den Velde, 1978; Eikelenboom

et al, 1984), HL-A antigens (Renvoize, 1984), HL-A linked complement components (Neri *et al*, 1984), and ABO and rhesus blood groups (Renvoize, 1985) in AD patients may help to unravel the nature of this inheritance. However, important information on the relative aetiological contributions of heredity and environment in AD might be gained by the more traditional approach of studying concordance rates for the disease in monozygotic (MZ) and dizygotic (DZ) twins, relying on the fact that MZ twins are genetically identical, whereas DZ twins share only half their genes. If an increased concordance rate is observed in MZ compared with DZ twins, a genetic contribution to the aetiology is confirmed.

Kallmann (1956) studied 108 twin pairs in which the index twin had senile dementia, and found an incidence of senile dementia of 42.8% in MZ co-twins, 8% in DZ co-twins, 6.5% in siblings and 3.4% in parents. Though this confirms the role of inheritance in senile dementia, the lack of full concordance in the MZ twins also points to the importance of non-genetic factors. No similar systematic twin studies have been conducted in the presenile form of

AD, and only four cases of PDAT occurring in identical twins have been described (Davidson & Robertson, 1955; Hunter *et al*, 1972; Sharman *et al*, 1979; Kilpatrick *et al*, 1983). This paucity of twin studies therefore prompts us to report a case of genetically proven MZ female twins, discordant for PDAT 20 years after the onset of disease in the affected twin.

Case report

Personal histories

The twins were born following an uncomplicated delivery in 1915, each weighing approximately 6 lbs; the unaffected twin (U) was born first and the affected twin (A) second. From birth they were identical in appearance, and later blood group studies showed a high probability (0.98) of them being monozygous (Table I). The personal development and educational progress of the twins was similar and unremarkable. Both left school at 14 to work as weavers in the same mill. Twin U married at 21 and moved away, while twin A married at 23 and lived locally, but they remained close, visited regularly, and went on holiday together. A was healthy prior to the onset of dementia and, unlike U, never travelled abroad. U had pneumonia at 16, appendicectomy at 20, mastectomy at 29 for a breast abscess, and suffered a left central retinal vein occlusion on the day of A's death at the age of 64. Both experienced the menopause at 44.

Twin U is widowed and lives alone. When interviewed, 20 years after the onset of PDAT in A, she showed no evidence of dementia, and scored maximum points on Hodkinson's Mental Test (1973).

Family history

Their father died of bronchopneumonia at the age of 65, and their mother, who developed insulin-dependent diabetes mellitus in later life, died from heart disease at 75. Neither the parents nor the grandparents appear to have become demented. Sisters of 72 and 60, and a brother of 62, are healthy and show no evidence of dementia.

Each twin had one daughter. The 41 year-old daughter of twin A is well, but the 43 year-old daughter of twin U was diagnosed as suffering from probable Hodgkin's disease at the age of 20. This is of interest in view of reports of an excess of myelo-proliferative disorders among the relatives of sufferers of AD (Heston *et al*, 1981). She presented with swelling in the left inguinal region, and a gland was removed which showed atypical histological features; she was treated with local radiation and made a full recovery, which has been sustained.

History of illness in the affected twin A

In 1964, at the age of 49, twin A began to have difficulty in setting the table, and forgot the names of old friends. Over the next four years there was a gradual decline in memory, intellect, and personality. During a hospital admission in 1968 she was restless, and disorientated in time, place

and person, concentration was poor, general information limited, and short and long-term memory impaired. She stammered and showed severe sensory, nominal and expressive dysphasia, with constructional apraxia and dyscalculia.

Physically she was a plump, normotensive, grey-haired woman, with bilateral arcus senilis, and slightly increased tendon reflexes in the limbs of the left side. Full blood count, erythrocyte sedimentation rate, blood urea, electrolytes, liver function tests, glucose, folic acid and cyanocobalamin levels, thyroid function tests, and Wassermann reaction and Kahn tests were normal. Cerebrospinal fluid examination, including the Lange colloidal gold curve, was normal, as were skull and chest x-rays, air encephalogram, left carotid angiogram, electrocardiogram, and radioactive isotope brain scan. A series of EEGs showed abnormal activity of theta and delta frequency, symmetrically distributed, with subclinical seizure activity in one record.

After discharge she became progressively more dependent upon her husband, requiring help with feeding, washing, and dressing; she was finally admitted to a psychiatric hospital, four years later. She gradually became mute, unresponsive, wasted, doubly incontinent, bed-ridden, and prone to generalised seizures; at this stage, there was generalised hypertonia, hyper-reflexia, and occasional myoclonus. She died at the age of 64, about 15 years after the onset of dementia.

Post-mortem findings

The body was emaciated; all the visceral organs were underweight, and there was a severe bronchopneumonia.

The brain weighed 850 g, and externally showed marked generalised cortical atrophy, maximal at the frontal poles. Coronal sectioning revealed the cerebral ventricles to be dilated and the cerebral cortex thinned, especially in the occipital region, the subcortical structures were relatively normal.

Microscopically, senile plaques were found in the cerebral cortex in sections from the temporal, frontal, parietal, and occipital regions. In frozen sections of the temporal lobe these plaques were numerous, and many of the cortical neurons showed neurofibrillary tangles. The appearances were those of AD.

Discussion

Our case is the third example in the literature of MZ twin pairs discordant for PDAT. Davidson & Robertson (1955) reported a woman with acne rosacea who began to dement at the age of 50, and died 19 years later. The post-mortem confirmed AD; her unaffected twin sister showed no evidence of dementia at the age of 73. These twins were considered to be identical, although no laboratory investigations were made to prove uni-ovularity. The affected twin had suffered from severe influenza with delirium and fever at the age of 38, during the 1918-1919 epidemic; as in our case, the affected twin was the second-born, and there was no family history of dementia. Hunter *et al* (1972) also described a pair of genetically proven MZ female twins discordant for PDAT. The affected twin died aged 64, after a 15-year history of dementia; AD was confirmed at post-mortem. The unaffected twin sister died two years later of carcinoma. As the twins had been adopted in infancy, no details of birth order or family history were available. Our twin A and the affected twins described above have some features in common: all were women with similar ages at onset and with illnesses of unusually long duration.

There are two reports of MZ twins concordant for PDAT. Sharman *et al* (1979) described PDAT in identical twin brothers who simultaneously developed the disease at the age of 34 and who both died four years later. The disease was confirmed histologically in both, but no special genetic studies were carried out to prove monozygosity. Their mother had also developed a similar dementing illness at the age of 37 and died five years later; at post-mortem her brain was found to be atrophied, but no histological examination was performed. More recently,

Kilpatrick *et al* (1983) reported genetically proven identical twin sisters with PDAT, both of whom started to dement at the age of 50 and were still alive six years later. Histological confirmation of the disease was obtained by cortical biopsy in both sisters. Their mother and maternal grandmother had developed a similar illness at the same age. The almost simultaneous onset of dementia and the positive family history in these two twin pairs favours autosomal dominant inheritance.

Although concordance cannot be completely excluded in our twins, it is unlikely after 20 years; as both twins were genetically identical, this discordance points to the importance of environmental influences in the onset of AD in the affected twin. Potential aetiological factors already examined in the disease include disordered immune function (Kellett *et al*, 1982; Pentland *et al*, 1982), conventional virus infections (Whalley *et al*, 1980; Renvoize & Hambling, 1984), chromosomal abnormalities (Wright & Whalley, 1984), and metal intoxications (Crappier *et al*, 1976; McDermott *et al*, 1979), but no clear associations have as yet emerged. In a case-control study of AD, Heyman *et al* (1984) found no differences between patients and controls in toxic environmental exposures, animal contacts, smoking, drinking, or unusual dietary habits; however, AD patients had an increased history of severe head injury, and female patients a higher frequency of prior thyroid disease.

Although the role of inheritance in the aetiology of AD is clearly established, this and previous reports of twins discordant for the disease demonstrate that non-genetic factors must also play a part, at least in some cases. The search to identify these environmental agents should continue.

Acknowledgements

We are grateful to twin U, twin A's husband, Dr L. A. Derrick Tovey, Mr R. B. Harcourt, Dr G. M. King, and Mrs Elizabeth Tuxford. This work was supported by a grant to Dr Renvoize from the British Foundation for Age Research.

Art Group Psychotherapy in a Psychiatric Day Unit

The use of art in the context of a therapy group in a day hospital setting is described, and the literature on art and factors influencing such groups discussed.

Art has been used to illuminate psychopathology (Rorschach, 1913; Guttmann & Maclay, 1937; Maclay *et al.*, 1938; Lehmann & Risquez, 1953; Wadeson & Bunney, 1970; Birtchnell, 1973), as an indicator of maturation (Richards & Ross, 1967), as the main agent in the rehabilitation of psychiatric patients (Dreikurs, 1976), and as an adjuvant in a therapy programme (Edelstein & Kneller, 1976). It has also been used as an aid to counter institutionalisation (Gerace & Rosenberg, 1979) and to sensitise staff to the feelings of their patients (Misner, 1979).

Method

The project was set up to meet the needs of a group of day patients at the Department of Psychological Medicine, Newcastle General Hospital. The group comprised the Senior Registrar in Psychiatry and Art Therapist as therapists, with six patients whom it was felt could benefit from psychodynamic group therapy. It was planned as a 'slow open' group, since members were free to leave after an initial commitment of three months. However, with only one member leaving after six months to find employment outside the city, it became a 'closed' group.

The group met once weekly for one and a half hours, over one year. The first hour was a conventional talking group, followed by about 15 minutes' painting; a further 15 minutes was spent discussing the individual paintings of the patients and therapists.

The group was older (range 40–58 years) and more chronically disturbed (2–8 years of psychiatric treatment) than is usual for therapy groups, but quite characteristic of patients in most day hospitals. The group members each demonstrated a combination of symptomatic disturbance, dependent patient role, interpersonal problems, and problems of self-concept. They were of average or above average intelligence, with varying verbal ability and even more variable psychological mindedness. Assessment for the group was on the basis of each patient's personal characteristics and on their ability to use other group activities on the Unit.

The therapists had detailed discussions about the verbal content and paintings after each therapy session. This self-supervision was enhanced by writing up each session and presenting this to the supervisor each month. An assessment of outcome was made six months after the end of the group, in order to avoid the immediate effects of the ending of a group and yet to be recent enough for the group to be remembered clearly (Bednar & Lawlis, 1971). Moreover, sustained gains are more important than gains apparent immediately after treatment. To avoid therapist bias, the patient and referring psychiatrists rated changes (in mood, interpersonal functioning, and 'overall') since referral to the day unit. Patients rated components of their experience in the group.

Case History and Results

The experience of the group can best be illustrated by describing one of the patients. Analysis of the effects of

therapy with a group of six is necessarily anecdotal rather than statistical.

Mrs F, aged 51, had her first psychiatric illness two years previously, when she was admitted with loss of confidence, apprehension, shakiness, anxiety, and depression; the diagnosis then was depressive illness. She had previously been treated by her GP for five years. On admission, she received tricyclic antidepressants and ECT. She responded to these, but was left with marked loss of confidence and self-esteem, having lost her job on account of prolonged absence from work. She had a broken marriage, but was continuing to stay in the same house with her ex-husband and sons.

The symbols in her paintings expressed her attitude towards the group by portraying them as trees under black skies, representing non-coping people. To convey her feelings of isolation and uncertainties about becoming part of a group she positioned herself as a raft, looking towards the mainland where she felt she should be, but with a hostile sea of emotions to cross before she could reach land. As the group progressed and strong feelings were being expressed, she showed apprehension by painting a crouched figure waiting to be protected, or half-constructed walls, not knowing whether they should be built up or broken down. She also saw herself as a leper hiding in a hooded cloak – a diseased person not acceptable to 'normal' society – and the group as scared people who wore masks in order to appear 'normal'. Her anger was expressed against this society in a drawing of herself as a rat in a cage, being rewarded with a piece of cheese for performing well. As she worked through her feelings, she drew defences which were strong enough to cope with landslides of the future. As the group approached its end, she was afraid she would not cope without its support, and showed anger at the impending loss. She compared herself to a toad which hibernates in a hole during adverse conditions, where it stays, feeds, and swells so much that it cannot leave the hole when it wants to. However, she worked through the pain of the loss, the effort involved being symbolised by climbing a long steep ladder to leave. Mrs F painted quickly and spontaneously, covering most of the paper. In discussions she could express anger and distress, which also emerged in the painting, and in times of distress she could use the painting as a means of cathartic release, communicating to the group her conflicts and her responses. She showed an ability to respond to other group members, and to integrate her interactions so as to gain understanding of her feelings.

Six months after the group, Mrs F felt much better generally in her mood and in her relationships. She had found all aspects of the group helpful, and was only disappointed that it had not gone on longer. The psychiatrist had discharged her from his care, feeling that she had improved greatly overall and in her mood, but only slightly in her relationships; he noted that the group had helped her self-esteem and enabled her to express her anger and other emotions instead of storing them up.

Another group member showed gains comparable to Mrs F, and a further member gave every indication of similar improvement before his death from a myocardial infarct three months after the end of the group. The patient who left after six months had made significant improvements; the other two members rated themselves as unchanged or

worse, though their referring psychiatrists thought that their functioning was marginally better. Their lack of progress after the group had been reflected in a lack of progression in the themes of their paintings during therapy. It is of interest that this is in keeping with Kiesler's view (1971) that indicators of progress can be indicators of eventual outcome.

Discussion

A veture of this kind raises such questions as the balance between caring and curing for patients who are older, less flexible, and have less overall strengths to contribute to the life of the group, yet who bring a longer lifespan of experience and stability to therapy (Hildebrand, 1982). Questions that are related to this issue are: How 'real' and accessible should the therapist be? Is therapy to be skewed in the direction of 'non-specific' therapeutic factors (Yalom, 1975; Bloch, 1979), such as catharsis, mutual support, universality of problems and altruism between group members (all very evident in this group), or of relating present, 'here and now' feelings to transference issues in the past and current external present (Malan, 1979)?

Transference issues appear less important in older patients (Hildebrand, 1982). This is reinforced both by a closing down in the range of options available and by painful feelings in relation to a longer adult life, in which mistakes have been made whose transference implications have been overlaid with more practical consequences. This difference of perspective is easily lost on therapists more youthful than their patients unless, as in this group, they have had considerable experience with older patients.

As part of the assessment procedure of the day unit, all patients were encouraged to be aware of the interpersonal aspects of their problems, and to regard their situation in wider terms than 'illness' and the relief of symptoms. The very nature of conducting the group in a day unit programme both enriched, supported, and complicated the therapy. It enriched it by common day-by-day experience shared by patients and therapists. It supported it, as shown by the very high attendance and negligible dropout rate, and complicated it by presenting opportunities for acting out group phenomena on the unit. Meeting between sessions in a fairly structured setting provided an opportunity to work through material informally. While the general intervention of the therapists was directed to commenting on here-and-now events in the group, relating these

to current and past events, their role as interpreters was affected by their roles outside the group.

The supervisor addressed himself to the written reported content of the sessions and to the paintings as they were produced; in this way the therapists were encouraged to work over the issues between sessions, committing their thoughts to paper. Since the supervisor saw his role as that of supervisor and not therapist to the therapists, his comments on the therapists' paintings were handled in much the same way as the reported verbal material.

For this group the art component played diverse roles. The paintings gave insight into the personality styles of the group members and the degree to which these changed. As well as these 'diagnostic' perspectives, the art reinforced a sense of identity among group members, which contrasted with their former role as recipient patients, and thus it discouraged institutionalisation and encouraged group cohesion. It was an adjuvant to the therapy itself, serving to sensitise staff to the feelings of their patients, both in an overall sense and also towards the changing feelings within the group. While the therapists' paintings reflected their roles and feelings in relation to the group processes, the patient's paintings could be interpreted both personally and as carrying some aspect of the group dynamic.

For some group members, painting enabled them to communicate with the group in a way that would have been denied them had the group been entirely verbal. This is important for people who, for intellectual, educational, or cultural reasons, do not readily express themselves verbally. For others, art represented a sublimated discharge of the feelings mobilised in the course of therapy. It may be questioned whether such a group safeguarded some members from acting out their feelings in a less controlled manner in their lives. To people who have suffered considerable emotional and material deprivation, apparently uninvolved therapists can be seen as being further depriving, and are likely to be ignored or reacted to with much hostility (Meares & Hobson, 1977). The therapists avoided this problem by combining an interpretive with a more giving role, both by sharing the act of painting and by contact with group members in the day unit at other times.

A Comparison of the Antidepressant Action of Citalopram and Amitriptyline

The response of patients with major depressive illness to citalopram of amitriptyline was compared in a double-blind multi-centre trial. No differences in efficacy were observed, but citalopram had less hypnotic effect, and a remarkably lower profile of side-effects.

Citalopram is unrelated to tricyclic, tetracyclic, or other known antidepressants, and is a specific blocker of neuronal uptake of 5-hydroxytryptamine at the presynaptic membrane, with no significant action on catecholaminergic systems. Its pharmacological properties suggested that it should be non-toxic to the heart, and without anticholinergic side-effects.

Method

The trial was conducted in five hospitals in South Wales, on in-patients and out-patients aged between 18 and 70 who met the DSM-III criteria for major depressive illness (American Psychiatric Association, 1980), scored 18 or more on the 17-item Hamilton Rating Scale for Depression (HRSD) (Hamilton, 1967), and gave informed consent. All were entered into the trial within 36 hours of admission (48 hours at weekends).

The trial was double-blind and randomised in blocks of four. Matching tablets contained either 10 mg of citalopram or 37.5 mg of amitriptyline. For the first three days the dose was two tablets at night, increasing to four until the end of the third week, and thereafter 3–6 tablets (30–60 mg citalopram, 112.5–225 mg amitriptyline). Average doses given in the sixth week were 46 mg for citalopram and 148 mg for amitriptyline. The only other drugs allowed were diazepam and temazepam, for night sedation and for control of anxiety.

The trial lasted six weeks, but some patients were withdrawn earlier for troublesome side-effects persisting after reducing the dose (one patient on citalopram, five on amitriptyline), for deterioration or failure to improve (four and five, respectively) and for other reasons (two and five, respectively).

The following assessments were made: the Newcastle Scale (Carney *et al.*, 1965), the HRSD; the Montgomery-Åsberg Depression Rating Scale (MADRAS) (Montgomery & Åsberg, 1979); and the Leeds Self-Rating Depression Scale (Snaith *et al.*, 1976). The results were analysed using the Mann-Whitney U-test, the Wilcoxon matched pairs signed ranks test, and the chi-squared test.

The assessments of efficacy were run as end-point analyses, transferring the latest available rating to later assessments. Of the 24 allocated to citalopram, one was assessed only up to three weeks, one to the fourth week of treatment, and the remainder completed the six weeks' course. Two on amitriptyline were assessed for the last time at three weeks, three at four weeks, and the remainder of the 20 remained on the trial for six weeks.

The mean data for the HDRS are illustrated in Fig. 1. The other assessments gave similar results, and have not been included. There were no significant differences between the groups in the average starting scores on any of these ratings, or between any of the subsequent scores. All ratings showed a significant improvement at the 5% level from seven days onwards (Wilcoxon matched pairs).

Side effects

Most patients experienced at least one additional side-effect over baseline during treatment. In general, reported side-effects were much more common in those on amitriptyline (110) than in those taking citalopram (52) (Fig. 2), and the profiles of complaints appeared to be due to the anticholinergic properties of amitriptyline (dry mouth, blurred vision, sweating, urinary retention, and constipation). Of patients on citalopram, 16 had no such symptoms and 11 had one or more; of those on amitriptyline, only five were free of anticholinergic problems and 20 recorded one or more (χ^2 , $P < 0.01$). With citalopram, five side-effects of severe degree were reported, compared with twelve with amitriptyline.

Discussion

No difference in therapeutic effects of citalopram and

FIG. 1 Mean HDRS scores for citalopram ($n = 24$) and amitriptyline ($n = 20$). Error bars show the standard errors

FIG. 2 Side-effects not present at baseline

amitriptyline appeared, but citalopram was clearly the less troublesome drug with regard to side-effects, in that side-effects above baseline were seen twice as

often in the amitriptyline group. Amitriptyline's problems in this, as anticipated, were anticholinergic. Thus, the results of this trial suggest that citalopram is an effective and acceptable antidepressant.

Books Reconsidered

*Psychotherapy by Reciprocal Inhibition: Joseph Wolpe**

I first came across this particular book during my training at Boston City Hospital in 1970. It was by that time 12 years old. Skinnerian operant conditioning was the rage in the psychological and psychiatric circles; reciprocal inhibition seemed at the time to be considered *passé*. The psychoanalysts had already discounted any suggestion that the only effect of insight-oriented therapy was to provide a therapeutic setting in which reciprocal inhibition took place. Behaviour therapists were busy working out complex positive and negative reinforcement schedules for illnesses as diverse as schizophrenia and alcoholism. Dr Laing put in an appearance in Boston at that particular time, extolling the virtues of the existential benefits of madness. But, I imagine that in its day, this book was highly controversial, since it challenges the central premise of psychoanalysis—that the essence of psychotherapy is uncovering and expression of the repressed.

Wolpe presented a new theory of psychotherapy based on learning theory: neurotic behaviour is presented as originating in learning, and the theory predicts that its elimination is a matter of unlearning. Thus, the gauntlet was thrown down and psychoanalysis challenged. Wolpe introduces his ideas with experimental observations which were made on cats in which lasting neurotic states had been induced. Should anyone doubt that cats can be made neurotic, they need only discuss their current doubts with our sister profession, The Pet Psychiatrists. An antagonism between feeding responses and anxiety was found to occur.

It is this finding which was transposed into the realms of psychotherapy with humans. The therapeutic principle of reciprocal inhibition is as follows: "If a response antagonistic to anxiety can be made to occur in the presence of anxiety-evoking stimuli, so that it is accompanied by a complete or partial suppression of the anxiety responses, the bond between these stimuli and the anxiety responses will be weakened."

Wolpe's basic method was simple. An anxiety hierarchy was constructed with patients, and the patient was then made to relax (reciprocally inhibited), while

imagining items in the anxiety hierarchy. A 90% cure was claimed with neuroses from simple phobias through to character neuroses, which were believed to consist of intricate systems of phobias. The reciprocal inhibition which was used ranged from assertive responses, sexual responses, relaxation responses, respiratory responses, 'anxiety-relief' responses, conditioned motor responses, 'pleasant' responses in the life situation [with drug enhancement], and interview-induced emotional responses. These were the responses that the disposal of the therapist by which therapeutic change may deliberately be brought about.

Justification for this method is coherent and logical. A background explanation of the relationships between anatomical structures in behaviour, discussion about the making and unmaking of functional neural connections, in other words—learning and unlearning, are followed by a definition of neurotic behaviour—"any persistent habit of unadaptive behaviour acquired by learning in a physiologically normal organism."

My main criticism of *Reciprocal Inhibition* is that it oversimplifies the method by which human beings acquire neurotic illnesses. This oversimplification leads to a blinkered epistemology of the totality of human experience. Psychotherapy by reciprocal inhibition attempts to break the links between the person and extra-personal stimuli. The mistake of psychoanalysis initially was to ignore this very important area. The mistake in psychotherapy by reciprocal inhibition is to ignore the fact that human beings can create within themselves a world whose inner reality and experience bears little resemblance, if any, to the outer reality of the world within which that person lives. Hence, people have strong beliefs in religion, strong cravings for and addictions to various forms of art and culture; they also can internally (intrapsychically) create and maintain belief which leads to neurotic behaviour. Looking at a systemic level, the theory of reciprocal inhibition by-passes the power inherent in a system. Systems may condone certain types of symptoms, but condemn others. For example, one family may consider it is perfectly permissible for the entire family to bathe together in the nude, while another family exists in which such behaviour would be cause for

* (1958) Stanford University Press, California

instant referral to the nearest psychiatrist. In one therapeutic group it is permissible to stand up, shout, move about, roll on the ground, and regress to birth while in another therapeutic group, any such movement could lead to instant dismissal from the group.

But where is the strength of this book? I believe it lies in the systematic way that innovative, interesting, and successfully used therapeutic techniques and methods of treatment are presented. Why should it be re-read? In much of psychiatric practice, there remains extreme ignorance about creative ways of working with people. Psychotherapy using reciprocal inhibition actually includes the therapeutic relationship itself. I regret that much of the ignorance is within the psychiatric profession, while much of the psychological work is being done by psychologists,

nurses, social workers, and occupational therapists. Many of them will already have absorbed the principles of psychotherapy by reciprocal inhibition, and because they are unable to prescribe and use drugs, they have forged ahead in their abilities to use their relationship with patients in an effective way.

When the Royal College of Psychiatrists feels that psychotherapy training of any sort should not be made mandatory for junior psychiatrists, it will not surprise me that recommendations that this book be read by every junior psychiatrist would also fall on deaf ears. Nevertheless, I would make this recommendation. It is a book well worth reading and was written well before the polemics about behavioural therapy versus "analytical psychotherapy" destroyed any concordance that could have occurred within the psychiatric profession.

Dominance Hierarchies in Psychotherapy Groups

Sir: The article by Kennedy and McKenzie (*Journal*, June 1986, 148, 625-631) is fundamentally flawed. The underlying assumption of the authors is that social behaviour has biological determinants, and that the social behaviour of the highest organism phylogenetically will include the social behaviour of the lower primates, such as chimpanzees. In particular, the authors say there is a "natural" tendency to form hierarchies and furthermore, these hierarchies have a regulatory function, resolving the tension between the development of cohesion and conflict. The central error is to ignore the importance of culture and variation in human social organisation. It is not true that humans are "naturally" hierarchical. There is much research by social anthropologists describing in detail how many societies of people who live by hunting and gathering are, remarkably, non-hierarchical (e.g., Lee & DeVore, 1968). Amongst some hunters and gatherers there is a leader whose position is attributable as much to personality factors as his skill in hunting; however there are no ways to impose his authority, and his position is very tenuous. When conflicts arise the hunting band is likely to divide.

Many anthropologists (e.g., Sahlins, 1977) consider direct extrapolation from ethnological studies to human behaviour to be an abuse of the method. One reason why this occurs is that aspects of social organisation, the culture, of the writers are seen in the animal society organisation.

This is made relevant in considering the subject of hierarchies in psychotherapy groups: these groups share the culture of the society of which they are a part. When the authors see hierarchy in psychotherapy groups they will consider it to be "natural". They are, in fact, seeing the way the group reproduces the outside social structure.

ECT as a Contributor to the Production of Delusional Misidentification

Sir: I read with interest the conclusion of Dr Hay's paper (*Journal*, June 1986, 148, 667-669).

I have seen a 58 year old woman who presented with a three week history of delusional misrepresentation which began after she had an anaesthetic. She had become constipated with the onset of a depressive illness two months previously, and believed that she had cancer. She sought a surgical opinion. A sigmoidoscopy was performed under anaesthetic which excluded bowel pathology, but confirmed constipation. She had suffered no previous psychiatric illness. Both the patient and her husband agreed that the delusional misidentification began after the sigmoidoscopy. This suggests that an anaesthetic agent rather than electrical stimulation may be the cause of such symptoms.

Lithium Augmentation of Tricyclics

Sir: Pai *et al* (*Journal*, June 1986, 148, 736-738) describe a further series of patients where it is claimed that lithium augments the effects of another antidepressant. Nearly all the other studies making this claim, including those cited in the report, seem to be describing the same phenomenon. Namely, that some severely depressed patients who have completely failed to respond to a first-line antidepressant dramatically respond within anything from a few days to a couple of weeks to the addition of lithium. The simplest and most economical explanation of nearly all of the cases reported is that lithium has had a major acute antidepressant effect. Although most of the authors consider this possibility, it is usually dismissed and some complicated explanation for either summation or potentiation is invoked to explain the observation.

All of the controlled studies of the acute antidepressant effects of lithium, subsequent to the negative result of Stokes *et al* (1971) have shown lithium to have a major acute antidepressant effect, substantially better than placebo and at least, if not better, than an antidepressant such as imipramine.

Two controlled trials conducted by myself and colleagues in Dundee (Worrall *et al.*, 1979) are representative and discussed the issues at that time. One of those trials, in which tryptophan was compared with lithium and tryptophan in combination, is regularly quoted in the subsequent combined studies and used as evidence for lithium having an augmenting effect on other antidepressants. We specifically stated that the design of that trial could not possibly prove that. The simplest explanation in that trial was that lithium was acting alone and, in truth, tryptophan was only used because we did not obtain ethical permission for a placebo comparison.

What seems to have happened is that influential figures twenty years ago stated that lithium did not have important acute antidepressant effects and, with minor modifications, that statement has been authoritatively repeated in nearly all reviews since. What the combined studies have shown is that when a first-line treatment has proved ineffective and the clinician has then tried lithium, he has not believed his own eyes when he has seen a major acute antidepressant response, and some form of potentiation or augmentation of the first drug by lithium is instead suggested.

Why expose patients simultaneously to two drugs without first trying each separately, especially if, as is likely, continuation treatment is going to be needed? It may be that in a few patients lithium does need to be used along with another antidepressant, or a neuroleptic, and it would be surprising if on occasion two antidepressants from a different class did not have more effect than one. A controlled trial to prove that would be feasible, but before going to that trouble an open-minded reappraisal of the effects of lithium alone might make such a trial less necessary.

At Risk Drinking

Sir: I was delighted to read the article by Dr King (*Journal*, May 1986, **148**, 533-540). In this and other articles Dr King has used the CAGE Questionnaire.

Unfortunately, he has repeated a failure of other authors to attribute the questionnaire to the correct source. The CAGE questions were developed by me and my colleagues at the University of North Carolina in the late 1960s. The CAGE questions have been used in many different studies by now, and recently (Ewing, 1984) I published a paper in the *Journal of the American Medical Association* describing their origins, clinical use and efficacy. That reference might be the best one for Dr King and others to use in future.

Anhedonic Depression

Sir: Young *et al.* (*Journal*, March 1986, **148**, 257-267) have suggested the possible existence of two sub-types of endogenous depression—anhedonic sub-type and vegetative sub-type. Earlier, Hibbert *et al.* (1984) reported that symptoms of reduced interest and pleasure and of low mood represent features of the state of depression which are related to each other, but are not much related to the more 'biological' symptoms of reduced sleep and appetite.

In a study of 34 RDC major depressives, I classified the patients as anhedonic and non-anhedonic based on high or low scores on the sub-scale anhedonia-asociality of the Scale for the Assessment of Negative symptoms (SANS) (Andreasen, 1981). The anhedonic sub-type had a significantly ($P < 0.001$) longer duration of illness than the non-anhedonic sub-type. Almost 20% of anhedonic depressives had a duration of illness longer than nine months with treatment. The response to tricyclic antidepressants was unsatisfactory in the anhedonic depressives and the need for adjuvant therapy with electroconvulsive shocks and antipsychotics was significantly ($P < 0.01$) more often required for them. Anhedonic depressives also required a much longer duration of treatment than the non-anhedonic depressives (Chaturvedi & Sarmukaddam, 1986). Interestingly, anhedonic depressives had significantly higher total scores on SANS than non-anhedonic depressives.

These findings help further in identifying an anhedonic sub-type of depression. However, in my study, no demographic differences were observed

between the two groups, especially as regards, age, sex, education, occupation or marital status. There is a need for research on biological parameters to further validate the sub-types.

Quetelet's Index and Appetite and Weight Change in the Context of Depression

Sir: A study of 168 mild to moderately depressed out-patients presenting over a period of six years at St Thomas's Hospital, London, and involved in a series of antidepressant trials, showed that factors linked to appetite and weight change were previous appetite and weight history. Patients gaining appetite and weight with depression had a previous history of overeating in response to the normal stresses and strains of everyday life, and of variable weight history (Harris *et al*, 1984a). With recovery after six weeks' treatment, these patients tended to lose appetite and weight (Harris *et al*, 1984b). A possible explanation for this is to be found in the concept of restraint. According to Polivy & Herman (1976) restraint is characterised by preoccupation with the caloric values of food, dieting, and guilt feeling on diet-breaking. It is high in obese and latently obese subjects, and in normal or even under-weight individuals who respond to societal pressure to be slimmer and run below their "set-points" of body weight. They hypothesised that with anxiety and depression such individuals lose restraint, and there is increase in food intake and weight. Obviously, in large populations of depressives, there will be overlap with factors linked to obesity, and the further question arises as to whether or not it is the fatter patients (i.e., fat relative to height, not fat relative to pre-episode weight), who gain appetite and weight with depression and then lose appetite and weight with recovery. To examine this, we looked at subjects in terms of Quetelet's Index (QI) Weight/Height^2 (Quetelet, 1869). QI has recently been validated as a convenient formula and reliable indicator of obesity (Garrow & Webster, 1985): 20-24.9 representing

desirable weight, 25-30 mild overweight, and over 30 being clinically relevant.

The method of the study has been reported elsewhere (Harris *et al*, 1984a). At presentation, height and weight were measured, and after six weeks' treatment, patients were weighed again. QI was calculated in terms of the patient's stated normal weight. Appetite was scored at presentation and at six weeks, relative to patient's own norm. Standard statistical methods were used, including the unpaired t-test and the product-moment correlation coefficient.

Appetite and QI. At presentation, appetite was more often reduced than increased, and the relative appetite was positively correlated with QI ($r=0.15$ $0.05 < P < 0.1$). After six weeks' treatment this was reversed and there was a negative association between appetite and QI ($r=0.18$ $P < 0.05$). The patients were also divided according to appetite into groups with marked increase, moderate change and marked decrease. These groups were delineated by boundaries approximately one standard deviation either side of the mean. If delineation was by initial appetite, the differences between groups were not significant. When groups defined by appetite at six weeks were examined, subjects whose appetite was severely decreased were significantly fatter (QI mean 28.2) in comparison with those who had both marked increase and moderate change ($P < 0.01$). When projected back to what they were at presentation, the same group had had relatively high appetite.

Weight and QI. Weight at presentation showed no significant associations with QI. Patients were also divided into three groups: those with marked increase in weight (109% of their normal weight), those with moderate change (95 to 109% of normal), and those with marked decrease in weight (95% of normal weight). These groups were delineated by one standard deviation beyond the mean (102%). There were no significant differences at presentation but at six weeks the group currently less than 95% of customary body weight had a higher mean customary QI of 25.8 ($P < 0.05$).

A number of practical implications result from our findings concerning QI. First, there is a tendency for fatter individuals to increase appetite with depression. Therefore, identification and management of depressive mood changes is an important factor in the management of obesity. Secondly, the question arises as to whether or not further weight gain will occur with antidepressant treatment, e.g., due to tricyclic-induced carbohydrate craving. Our findings indicate that in the short term this is not the case, but that loss of appetite occurs, probably due to regain of control. It might be possible, therefore, to use a first line antidepressant drug such as a tricyclic

for a short period without producing further appetite and weight gain.

Smoking in Chronic Schizophrenia

Sir: While studying obesity in our patients (Gopalaswamy & Morgan, 1985) we asked them about their smoking habits and 100 men and 70 women replied: 123 of them had chronic schizophrenia, most were in their 50's and 60's with many years of illness behind them, 82% had never been married, and the majority were working class.

Smoking was more prevalent among the men ($P < 0.05$) and among the schizophrenic patients ($P < 0.001$): 87% of the men and 74% of the women schizophrenic patients smoked, compared with 60% and 58% respectively among the non-schizophrenic patients. These differences within the patient sample were trivial compared with the significant differences among the patients (83% of all men and 67% of all women smoked) and among the general population, of whom 36% of men and 32% women are known to smoke.

The proportion of smokers in the general population falls year by year in response to anti-smoking propaganda which most patients choose not to heed. This is very understandable. There may be few pleasures left in life for a person with chronic schizophrenia and smoking may be one of them. Indeed, for the schizophrenic it may be even more pleasurable than for a healthy person. Nicotine in large doses depresses a person's level of arousal. Schizophrenics suffer from heightened arousal and for them a packet of cigarettes represents a way of suppressing the discomfort of hyper-arousal which they may find more acceptable and effective than the major tranquillisers which we prescribe for them.

Our findings match quite closely those of Masterson & O'Shea (1984) who reported smoking by 92% of their male and 82% of their female schizophrenics. Rice (1979) questioned how heavily his schizophrenic patients smoked and whether they ever developed lung cancer. The proportion of patients with schizophrenia who die of lung cancer is surprisingly no higher, and may even be slightly lower, than in the general population—when it seems that it ought to be double or treble (O'Shea, 1984 Craig & Lin, 1981). This suggests either that people with schizophrenia enjoy partial protection against developing lung cancer or that cigarette smoking is not such an important aetiological factor as is thought. Either way the subject requires fuller investigation.

Psychotherapy in the Third Reich

Sir: Henry Rollin (*Journal*, March 1986, 148, 345-346) reminds us that the ghost of Hitler still stalks the world. I am reminded of an anecdote told by the late Willie Mayer-Gross, himself a victim of Nazi oppression, about the high esteem in which Hitler was held by some psychiatrists. A German research fellow working at the Maudsley came to see Mapother after the Reichstag fire and the plebiscite in 1932. He wanted to discontinue his fellowship and return to the Fatherland. "If 92% of the German people have voted for Hitler, he must be a great man". Mapother replied: "I am of Irish stock, if 92% of the Irish would vote for one man I would be certain that he is worthless".

Mayer-Gross' own researches into the fate of neurotics under the Third Reich confirmed the pathologic influence of culture on the manifestations of neuroses. Comparatively few German servicemen were shot for "lack of moral fibre"; neurotic anxiety and depression were somatised, generally taking the

form of disorders of the gastrointestinal tract. So great were their numbers that special "stomach battalions" were required to accommodate them and their disabilities. Hitler thought he had eliminated neurosis by decree: he did not succeed.

Tardive Dystonia and Pisa Syndrome

Sir: I wish to report a case of tardive dystonia presenting as Pisa syndrome and induced by depot neuroleptic.

Case report A 37 year old male patient with paranoid schizophrenia was on a maintenance dose of fluphenazine decanoate, 25 mg intramuscular every two weeks since May, 1981. Before that he had been treated as an in-patient during 1979 and 1981 with chlorpromazine up to 600 mg per day and five modified bilateral ECT. He had no family history of psychosis or any movement disorder. In June 1984 he was noticed to be keeping his upper trunk bent towards his left side and rotated backwards. This symptom had appeared insidiously and had been progressing slowly for about two months before he was brought to hospital. On examination, his left shoulder was tilted approximately four inches lower and two inches backwards compared to the right one. The patient could maintain normal posture only for a few minutes, with effort. There was no tremor or dyskinesic movement of any part of the body. The patient did not feel distressed or disabled by the symptom and, on questioning, showed marked lack of concern about his grossly abnormal posture.

His fluphenazine injections were discontinued and he was prescribed oral trihexyphenidyl 2 mg three times a day. However, there was no significant relief over four weeks and the drug was stopped. The patient was kept on drug-free follow-up. After another two months the symptom started improving slowly and disappeared completely by March, 1985. Since then there has been no recurrence and only residual schizophrenic symptoms are present for which he is not receiving medication.

The insidious onset of dystonia in this patient suggests the diagnosis of tardive dystonia. The symptom in this case matches almost exactly with the description of Pisa Syndrome (Ekblom *et al*, 1972; Yassa, 1985). Significant points to be noted here are absence of any acute dystonia or tardive dyskinesia at any stage, complete lack of concern shown by the patient to the symptom, unresponsiveness to anticholinergic therapy, and delayed but complete spontaneous recovery on discontinuation of fluphenazine.

Procyclidine Abuse

Sir: We wish to report five cases of procyclidine abuse.

Case reports. (i) A 39 year old man with a personality disorder (JB) insisted he needed chlorpromazine and procyclidine. When all his medication was stopped, his wife, a 26 year old schizophrenic adequately maintained on a depot neuroleptic, began requesting increasing amounts of procyclidine for persistent Parkinsonian side-effects. She later admitted that JB was using all her supply of the drug.

(ii) A 39 year old woman with schizophrenia regularly persuaded medical staff to prescribe procyclidine by telling tall stories such as: "the wind has blown away my prescription" and "the dog has eaten my tablets".

(iii) A 22 year old man with a personality disorder and a long history of polydrug abuse frequently presented to the casualty department at weekends feigning rigidity and oculogyric crises in order to obtain procyclidine.

(iv) A 58 year old man with schizophrenia refused procyclidine during his last hospital admission preferring instead to tolerate severe Parkinsonian side-effects. He said he was afraid of becoming addicted to procyclidine again.

(v) A 39 year old woman with schizophrenia refused to consider any reduction in her procyclidine dose even though she had no obvious side-effects from phenothiazine medication.

These cases illustrate abuse of procyclidine and the lengths to which patients may go in order to obtain it. The euphoric side-effects documented in the *British National Formulary* were cited by the patients as the main reason for their misuse of the drug. Dependence and abuse of procyclidine are not reported in the latest edition of the BNF.

Transcultural Psychiatry

Sir: Further to my anxieties about the use of psychiatry to confirm Western folklore concerning the *zombie* (*Journal*, March 1986, **148**, 340-341): it now appears that the Harvard research project on tetrodotoxin in Haiti was funded by the Broadway producer, David Merrick, and that the whole study is currently being turned into a feature film starring the

psychopharmacologist, his Haitian informants and, presumably, a *zombie* (Gleason, 1986). Apparently the original idea was that the drug, when isolated, would be used by NASA to place astronauts in a state of suspended animation during long voyages (Davis, 1986).

CORRECTION

In the letter from Anthony B. Joseph (*Journal*, June 1986, 148, 749) 5th para, 8th line, the reference should be (Joseph, 1986) not (Weinstein *et al*, 1954).

A HUNDRED YEARS AGO

The Idiots Bill

The framers of this measure should at once determine, not only in their own minds but by an intelligible definition of the term 'idiots' what class of persons they intend to deal with. As the Bill is drawn it is a highly unsatisfactory measure, affording opportunities for dealing with persons of feeble mind with only one certificate instead of two, and with the least possible protection. It will be a scandal if this measure passes with no more attempt to distinguish between two classes extremely easily confounded than the

absurd intimations that 'idiots' or 'imbeciles' do not include 'lunatics' or 'lunatic' does not mean or include 'idiot' or 'imbecile'. The definition is not one whit more intelligible as a means of analysis than the famous synthetical formula, "Caesar and Pompey are alike, especially Pompey."

Book Reviews

Foucault. By J. G. MERQUIOR. London: Fontana Press. 1985. Pp 188. £3.50.

Foucault was one of the celebrated twentieth century hermeneutic social thinkers who sought massive forces at work behind the unassuming social practices of the *bourgeoisie*. Like Marx, he was interested principally in power relationships (there is a chapter in this book on Foucault's 'cratology': his theory of power) but he ended up in Freudian territory in the power relationships which are codified in sexual practice.

Foucault is of interest to the psychiatrist as an ideologue and as a historian of insanity. Merquior is principally concerned to present the former side of him in this book, but does devote a chapter to *Madness and Civilization: A History of Insanity in the Age of Reason*, the gadfly book in which Foucault takes the great steps forward in psychiatry made by Pinel, Tuke and the rest, and argues for them being steps in "that gigantic moral imprisonment which we are in the habit of calling, doubtless by antiphrasis, the liberation of the insane by Pinel and Tuke" (*Madness and Civilization*, p. 278 in the Vintage Books edition). Merquior's discussion of this book closely follows the lines of Sedgwick's in *Psycho Politics*, but adds more evidence against Foucault's historical accuracy. In this chapter and later in the book, Merquior concludes that Foucault was not a reliable historian and that the true history of European psychiatry does not sustain his thesis.

Even so, the effect of *Madness and Civilization* lingers on, and not only in the camps of the irrationalists, the antipsychiatrists and the counter-culture to whom it made, according to Merquior, its first appeal. The reason for this may lie in the seductiveness of Foucault's central claims. Two of them are that modern man is an alienated and distorted descendant of men when unreason flourished; and that enlightened social reform, humane medical practice, sexual hygiene and scientific rationalism are some of the main means by which this distortion has come about since they represent the imposition on society of the apparatus to control unreason developed by the *bourgeoisie*.

Merquior assesses these and similar claims with impartiality although he makes clear that he is not a Foucaultian at the end of the book. It is a densely written monograph which draws on an impressive amount of research for its small compass. As is so

often the case, Foucault's style has affected the style of writing about Foucault and parts of the book seem purely rhetorical ("Like Nietzsche, Foucault holds the individual's will to power as a datum which is also an unavoidable fatum"). The learning is also sometimes too obtrusive, and the references to Foucault's books are sometimes to their French and sometimes to their very freely translated English titles, which makes for confusion. These minor criticisms aside, I enjoyed this book and I am glad to have read it. I would recommend it to any psychiatrist with an interest in the history of ideas or in recent currents of French intellectualism. It is also, insofar as I can judge, an excellent, if unsympathetic, introduction to the work of Foucault although it omits any indication of the relationship of that work to his life.

DIGBY TANTAM, *Senior Lecturer in Psychiatry, University of Manchester*

A DSM-III Casebook of Differential Therapeutics.

By SAMUEL PERRY, ALLEN FRANCES and JOHN CLARKIN. New York: Brunner/Mazel. 1985. Pp 370.

Case vignettes of 53 adult patients chosen to represent the spectrum of DSM-III diagnoses form the material upon which three authors from Cornell University display their skills in choice of psychiatric therapies. Their own cases are seasoned at times by those of distinguished colleagues from elsewhere in the USA and some cases of famous psychiatrists (Freud, Kraepelin and Alzheimer), whose management is now discussed in modern day terms. The purpose of this book is to illustrate the rationale of the various psychiatric therapies and, through their examples of putting therapies in to practice, to be educative. The book opens with a chapter that describes the various therapeutic options and closes with some personalised guidelines from the authors.

One of the strengths of this book is that it is well written with a lively style interspersed with humour. The cases read like short "who-dunnits", the outcome being held back while the clinician thinks aloud and chooses the therapeutic approach. The impact of that approach and the outcome for the patient is then presented. The second strength is that this book teaches us something about American/British differences in practice. Their treatments seem quite doctor

and clinic orientated, the relationship between the doctor and his patient being the key.

Paramedical and community workers are given little prominence. The approach by the psychiatrist is eclectic (somatic, behavioural and psychotherapeutic techniques all being used); but the bias is in favour of the last. In the introductory section to various therapies, 23 pages are given over to a discussion of interpersonal techniques while 3 are given to somatic therapies. However, for these authors the doctor/patient relationship is a precision instrument specified under the headings of format, setting, duration and frequency and technique. The authors point out possible dangers from the patient in misapplied relationships, so that throughout the book their therapeutic approach is carefully planned and monitored. Such critical analysis of the doctor/patient relationship, shown to be different in aim, type and duration for each of the patients they describe, is refreshing and very informative. The English reader can learn something here.

The weakness of the book comes perhaps from an implication in the title *A DSM-III Casebook*. While each case is classified along the five current DSM-III axes before treatment is discussed, the authors don't refer to this diagnostic exercise again. It would have been an excellent opportunity to evaluate DSM-III in terms of its ease of application in each of the cases and whether or not the classificatory exercise helped them in choice of treatment or had any predictive validity. This seems a wasted opportunity to show DSM-III in practice to an international readership. Time spent in critique would have perhaps given this book some balance because the overall effect is somewhat glossy. However, one mustn't carp too much, for it's rare to find a psychiatric text book that is enjoyable to read.

ANTHONY H. MANN, *Reader in Psychiatry,*
Royal Free Hospital School of Medicine, London

Essential Papers on Borderline Disorders. Edited by
MICHAEL H. STONE. New York: New York
University Press. 1986. Pp 580. \$55.00.

The time is ripe for an anthology of papers on the so-called borderline states or disorders. This volume provides an anthology which is the choice of a psychiatrist with broad interests in both the biological and psychoanalytic aspects of the problem, and it can therefore be read with interest by psychiatrists of all persuasions or none. It is one of a series of essential papers on psychoanalysis, the others being about object relations, narcissism, and depression respectively. Subtitled *One Hundred Years at the Border* it

takes up the story in 1835 with an extract from James Prichard's *Treatise on Insanity*. This is the third interpretation of Prichard's less than specific work, the others being the notions that he was writing about either psychopathy or manic depression.

Other papers in the 1880's to 1920's section are by Hughes and Rosse. Each section is preceded by a lengthy but helpful introduction written by the editor, setting the papers in historical context and trying to clarify the enormous logical and taxonomic difficulties which beset the field. Indeed these sections are perhaps value to the inexperienced reader than the selections themselves.

The second section deals with the analytic 30's and 40's, with contributions by Stern, Deutsch, Schmideberg, and Hoch and Polatin. Here the disorders in question are variously described as varieties of schizophrenia, psychopathy, and neuroses.

The 1950's and 60's contain papers by Grinker, Kety, Eriksen, Kernberg, and Balint, and show the beginnings of a biological approach and the flowering of the analytic. The 1970's and 80's are concerned with the nosological status as well as the tricky countertransference issues. The final paper, by Akiskal, carries the most telling title for borderline disorders—'Borderline: An Adjective in Search of a Noun'. It is to the credit of this volume that it does not try to shirk the problem of definition even though it may not throw much new light upon it.

The many different notions of what borderline is jostle each other in a nosological dustbin, sometimes perhaps without sufficient acknowledgment of the inconsistencies between them. They range from "moderately severe psychiatric disorders", through "mild, recovered and compensated schizophrenics" to *forme frustes* of either schizophrenia or, perhaps, manic depression (the bias, if any, of the editor). On a more personal note they may be "difficult narcissistic patients with whom one (ie the analyst) fails" or "angry depressed and unreasonable" patients. They may otherwise be classified as "hysteroid dysphoria", and even "mothers of borderline cases" are also said to be likely to be borderline.

Patients who show defence mechanisms of "disavowal and denial" or who have "serious problems in handling separation and in achieving an adequate sense of autonomy and self definition" can be called borderline. It fills "the space between existing and more sharply discriminable entities like schizophrenia and manic depression" and is neighbour to "concepts of psychoneurosis and schizophrenia", as well as having the two meanings carried in DSM-III of 'schizotypal' or 'unstable' personality. Only the concepts and definitions of Kohut are definitely rejected.

With such a plethora of descriptions the reader may be tempted to draw the conclusion that after more than a century at the borderline we still haven't got a map.

CHRISTOPHER THOMPSON, *Senior Lecturer,
Charing Cross and Westminster Medical School,
London*

Psychopharmacology: Recent Advances and Future Prospects. Edited by SUSAN D. IVERSEN. Oxford: Oxford University Press. 1985. Pp 332. £25.00.

For their tenth anniversary the British Association of Psychopharmacology decided on a broad review of their subject. The proceedings show variety as the striking feature, and specialists in modern psychopharmacology fill 27 chapters with history, progress, growing points, and further hopes and needs.

The work is divided into five parts, including affective disorders, anxiolytics, psychopharmacology of cognition, schizophrenia, and euphorians. In all it gives an impressive account of the status of the subject seen largely from the research-worker's point of view. The discussion of historical matters and areas of broader consideration will be readily enjoyed by all, but the more detailed chemistry is strong stuff, to be taken, if not slowly, in divided doses. Surprisingly, in the light of commercial pharmacological progress, affective disorders do not steal the limelight and the five sections are well balanced and thorough in approach.

The first section is concerned with the effectiveness of anti-depressants, and a helpful wide view of the treatment of depressive illness is taken, although the contributing factors in treatment resistance are not stressed. This is followed by consideration of the biology of depressive illness and the role of 5-HT. A detailed review of the role of platelets in the neurochemical field follows and there are clear and helpful descriptions of animal models of depression in which their limitations are fully acknowledged. Antidepressants of the future are considered.

In the second part, anxiolytic compounds are reviewed mainly from the point of view of the benzodiazepines; in particular where they act and their differences. There are chapters on the production of anxiety by drugs, and the prospects for treatment. This section is introduced by a stimulating and searching review of the uses of anxiolytic substances in society.

An additional treat is provided by a full section on cognitive disorders. Not only is the content important, but the introduction of this topic to the 'front window' of a major text may be "a first".

Schizophrenia receives a well-deserved share of research and particular attention is drawn to the contributions of genetics and environment, structural changes in the brain, the basis of antipsychotic drug activity, Dopamine D₂ receptors, and the case for integrated viral genes.

Medical consideration of stimulant drugs is still active despite their sunken public image. Perhaps the suggestion that there is little place for stimulant drugs in treatment may carry the baby with the bath water, for some find a limited place for them in excitatory abreaction techniques and the diagnosis of covert psychosis. The subject of alcohol is well covered and yields a worthy message. Caffeine, nicotine and aphrodisiacs are included here.

The variety of topics is equalled by the range of penetration and perspective shared by the chapters. Each justifies its inclusion. There are parts where the varied use of terms is irritating, but this is inevitable when drugs, chemistry or treatments themselves are the prime focus. In covering so wide a field the sentiments of the editor, Susan Iversen, bring us down to earth when she reminds us that the drugs discussed may improve brain function or restore dysfunction, but may also be instruments of self destruction. She should be congratulated, for this is a collection for the *cognoscent*, a clearly visible milestone of which the authors and British Association of Psychopharmacology should be proud.

JOHN POLLITT, *Consultant Psychiatrist,
Hayes Grove Priory Hospital*

Public Drinking and Public Policy. Edited by E. SINGLE and T. STORM. Toronto: Addiction Research Foundation. 1985. Pp 294. \$25.00 (hb), \$20.00 (pb).

Those of us involved in the delivery of services for people with drink-related problems find it increasingly hard to define the boundaries of our proper professional concern. We used to treat patients in hospital. Now we counsel customers in the Community. Concurrently we are becoming more interested in social contexts and conduct which may be prejudicial to reasonably problem free drinking. As our Community Services bite deeper and deeper into our drinking cultures, we cannot help but notice the regularity with which those for whom we care frequent the same drinking milieu, drink in the same peer groups with anti-domestic beliefs and/or which support and validate markedly high levels of alcoholisation. If, as we are urged, primary prevention and education are increasingly to become our business then so is an understanding and eventually perhaps a

moulding of public drinking behaviour. It is on that quite remote horizon of clinical practice that *Public Drinking and Public Policy* looms.

The book is the edited proceedings of an A.R.F. Conference held in Canada in April 1984 and obviously the participants had an exciting and illuminating time for the post-hoc introduction talks of the value of bringing together different groups and disciplines and the hope that the dialogue will be continuing. Generation of such sentiment is the life force of conferences but it is usually not sustained so that by the time the proceedings eventually see the light of day they are for the participants akin to old photographs and for readers who were not there, somebody else's photographs. So this book contains all the usual proceedings problems of repetition, inconsistency of style and striking differences of focus.

Most of the seventeen papers were given by social researchers and their techniques vary greatly. Some just sat on a bar stool drinking and watching what was going on (or participant observation as it is called) whereas others did huge international questionnaire surveys. What is pleasing is that regardless of the angle from which it was photographed the looming on the horizon was not formless. Young single men are the dominant pub goers; patrons' conduct is modified by the public house design and site; the bar staff have a major influence on drinking behaviour; price of drink and special offers such as "happy hours" do influence consumption and may lead to people making a decision to drink rather than do something else; neighbourhood taverns ("locals") are also about sociability and of course many pub environments are sexist. That's all pretty universal and has preventive potential. But the more unsystematised and quirky papers were the most illuminating. Pekka Sulkunen's chapter on a suburban pub in Finland and its darts club from the perspective firstly of the patrons and then of their wives or ex-wives is a delightful analysis. James Shaefer's highly original and idiosyncratic chapter which even includes a relationship between the tempo of country music and rate of consumption is a gem. (They are inversely correlated, probably because the slower is the music the more maudlin is the lyric.) Thomas Barbor's chapter on 'Alcohol, Economics and the Ecological Fallacy' is very condensed but well worth the effort and the final two chapters raise the interesting hare of the publican's liability if patrons drink and drive after leaving the establishment. This latter issue is exactly the kind—among thousands of others—to which David Robinson and Philip Tether address themselves in their important new book on local strategies for prevention of alcohol problems.

(*Preventing Alcohol Problems A Guide to Local Action*. London: Tavistock. 1985.)

So there is much here of interest but only to a tiny minority of specialists with a particular orientation. For the majority its main value would be to help them to understand what kind of environment they were in if after a hard week of "real psychiatry" they drop down for an hour or two to the Red Lion.

DOUGLAS CAMERON, *Consultant Psychiatrist,
Leicestershire Community Alcohol Service*

The Case-Study Method in Psychology and Related Disciplines. By D. B. BROMLEY. Chichester. John Wiley. 1986. Pp. 351. £24.50

Bromley's main contention is that the accepted methods of natural science, such as laboratory experiments and social surveys, cannot be easily applied to phenomena which have developed and occur in the 'real' world independently of investigators, particularly in individual cases. He believes that jurisprudence, especially the aspect concerned with 'best evidence', provides the basis of 'an explicit conceptual and methodological framework' (p. 312) which will solve the problem; hence his notion of the 'quasi-judicial' case-study - 'quasi' because of important differences between psychological and judicial case-studies. Bromley sees the case-study as utilising: i) all relevant information; ii) concepts and procedures derived from research, iii) the philosophy of science; and iv) the methods of other professional disciplines.

Bromley believes that the quasi-judicial case-study not only facilitates practical work, but can produce important generalisations, analogous to case-law. The case-study should therefore become one of the main investigative procedures of psychological science, being taught at both under- and post-graduate levels, publishing its own journals, and being prominent in formal academic discussions.

He does not demonstrate the exact relation of jurisprudence to psychological case-study method, and provides no empirical examples of the effective application of the method. We have only the discussion, very difficult to understand, of certain methodological and theoretical aspects of some unsystematic studies, which are only summarily described. The general account of the method is clearly written and very useful, but this account does not seem to differ, in essence, from the long-established practice of many clinical psychologists and psychiatrists.

The uniquely original aspect of this book lies in its conception of the scientific importance of the case study in general and clinical psychology, the exposition of which is enlivened by the imaginativeness of much of the writing. Further exploration of this conception could have important consequences for both psychiatry and clinical psychology.

M. B. SHAPIRO, *Honorary Research Fellow in Psychiatry,
University College, London*

Anxiety: Psychological Perspectives on Panic and Agoraphobia. By Richard S. Hallam. London: Academic Press 1985. Pp. 210 £30.

Panic: Facing Fears, Phobias and Anxiety. By Stewart Agras. New York: W. H. Freeman 1985. Pp. 151. £22.95 (hb), £13.95 (pb).

The first of these books is a long theoretical exploration of anxiety or rather certain aspects of that state of experience which the author chooses to call panic anxiety. Despite the title the first part of the work considers somatic aspects and medico-psychiatric views and constructs. It is at times difficult to be certain what the author means by the term 'panic-anxiety' but a chapter devoted to three illustrative accounts by subjects (sufferers) of their experience indicates that the area of discourse is concerned with sudden onset of anxiety which the subject recognises as an abnormal experience. Despite this the author strives to discount the abnormal, or morbid, nature of such an experience. The many strands of thought that entwine the topic are followed and this results in a useful survey of present views although the author admits his prejudice and some are more fully developed than others. The personal contribution of the authors is hard to discern. It is a book for a theoretician and not for a clinician.

Dr Agras' book is, by contrast, addressed to the intelligent person who suffers, or who has a relative suffering, from phobias. It might be read with benefit but it is constricted by the somewhat naive theoretical concepts of classical behaviour therapy and fails to develop the more enlightening cognitive reinterpretation of these views and clinical concepts. Despite the title there is no clear description of the state of panic disorder and no development of the observations which have led to an understanding of the development of agoraphobia from early panic attacks. Consequently the reader is uncertain as to the basic difference between the agoraphobic syndrome and other simple phobic states. The attempt to conceive of compulsive symptoms as a simple extension of phobic states has been discounted and the author confuses 'implosion therapy' with exposure to anxiety inducing situations at maximum intensity which is sometimes called flooding. Certainly implosion therapy did not originate from the Institute of Psychiatry, London. Despite these and other minor objections the book would do no harm if read by a phobic patient.

PHILIP SNAITH, *Senior Lecturer in Psychiatry,*
The University of Leeds

Preclinical Psychopharmacology. Vol. 2, Part 1 Edited by D. G. GRAHAM-SMITH and P. J. COWEN. Amsterdam Elsevier. 1985. Pp. 471. \$111.00, Dfl. 300.00.

"The route that pharmacology offers for a biological understanding of severe mental illness remains a difficult one", wrote one of the authors. Despite the interest and activity centered on psychopharmacology and biological psychiatry in recent years, and the exponentially increasing volume of literature, the major clinical breakthrough is as illusive as ever. This may change in the near future when numerous new and significantly different compounds,

currently under development by the drug industry, complete their clinical evaluations.

This multiauthor book, covers in depth, topics in pre-clinical psychopharmacology. The first part is about the basic classes of drugs with chapters on antidepressants, monoamine oxidase inhibitors, lithium, tranquillisers, psychostimulants, and neuroleptics. The second part is devoted to a review of drugs of abuse covering the psychopharmacology of the opiates, hallucinogens, cannabis, alcohol and cocaine and there is also a section on behavioural teratology and toxicology.

The large section on drugs of abuse including a chapter on PCP is topical. Interesting issues such as the often alluded but rarely quoted relationship between opiates, acupuncture and the placebo effect are also covered.

Issues which may be of particular interest to the psychiatrist include discussions about the 4 postulated dopamine receptors, and the several benzodiazepine ligands, their positive and negative actions and the possible clinical implications. New therapeutic approaches hinted at, include the search for an endogenous ligand for imipramine, presumably along the lines of an endorphin, and the suggestion that imipramine acts as an intraneural false transmitter.

The literary style is of a scientific review with copious references and cross references. One excellent chapter has over 600. Despite that, the book is readable and engagingly interesting. It does, however, presuppose a considerable background knowledge of the specifics of the subject in order to derive full benefit from the text.

This book deserves to be in every medical library and the bookshelves of those clinicians, academics and researchers with an active interest in the area. The slant of the book is clearly towards the preclinical aspects. It is not the book for a casual browser but an authoritative reference work.

COSMO HALLSTRÖM, *Consultant Psychiatrist,*
Charing Cross Hospital, London

Psychopathology Among Mentally Retarded Children and Adolescents - Developmental Clinical Psychology and Psychiatry 6. By JOHNNY L. MATSON and CYNTHIA L. FRAME. London. Sage Publications. 1986. Pp. 119. £19.75. (hb), £10.00 (pb).

This is one of a series of books on problems of children and adolescents designed to present the latest research, theory and trends in clinical practice together with the likely future direction of research in the field. This book, sixth in the series looks at behaviour disorders and emotional problems in children and adolescents with a mental handicap.

The point is made that there is so far little in the way of research and this has concentrated mainly on the less handicapped and the older child. Little has been done to understand the behavioural difficulties of the profoundly handicapped child and in particular the younger age group. The book makes the point that until recently behaviour disorders and mental retardation were often regarded as mutually exclusive diagnoses and points out the current trend of interest in this field which has already shown that the mentally retarded child has a greater risk of behaviour disorder in its widest sense than the child with normal intelligence.

There is a preoccupation with finding suitable objective measurements such as rating scales or adapting those in use in a population of normal intelligence. Clinicians in the UK will be unfamiliar with many of those discussed and will not have found the lack of such instruments a handicap in their everyday practice. It is surprising that many of the drugs mentioned in the section on pharmacotherapy are described by their trade name, which may limit the value of this section in the UK.

Child psychiatrists in training in this country are now being encouraged to include the mentally handicapped child and his family in their practice when there are psychological problems. Many established child psychiatrists are reluctant to encourage this trend, fearing that the mentally handicapped child will present with a discrete and insoluble range of difficulties bearing no relationship to the child of normal intelligence. I do not think that this book will help to dispel this myth and there is the risk that this book will prove de-killing to those who wish to know more about the child with a mental handicap in this country.

JOAN BICKNELL, *Professor of Mentally Subnormality, St George's Hospital Medical School, London*

Depression: A Psychobiological Synthesis. By Paul Willner. Chichester: John Wiley. 1985. Pp. 597. £57.50 \$80.65.

This book has been long overdue: it provides a near exhaustive review of the literature pertaining to the psychological and biological strands of depression with the aim of providing an explanatory psychobiological framework for the complex interaction of these aspects. The author has selectively sampled the literature on psychology, social aspects, physiology, chemical pathology and pharmacology of depression with a particular reference to animal models in a search for links between these strata of analysis before providing a synthesis. The contents of the book are well organised to achieve this aim. In Part 1, the nature of psychobiological explanations is exposed and this is followed by reviews of nosology, cognitive functioning, neuropsychology and of animal models. The chapters on animal models are excellent and examine the comparative validity of these models as they relate to the human situation. In Part 3, the involvement of specific transmitters is reviewed from standpoints of theory, the clinical situation and neuropharmacology, ending with a chapter on their interactions. These reviews, however, are essentially non-critical: shortcomings of methodology, sources of conflicting results of various studies were rarely exposed, which is germane to the aim of this monumental work if the construct provided is to have stability. Part 5, provides elements of a synthesis under aspects of etiology, psychopathology, natural history and effects of treatment ending with a brief summary and a statement on future directions. This final part is very succinctly and lucidly written, but would have been enhanced if the author had provided flow charts and diagrams to outline his framework. The model provided has heuristic value for researchers into 'missing links' and provides new insights into the phenomenon of depression. I found the book stimulating and it should appeal to clinicians and researchers with a broad approach

to the study and understanding of depression. The book has a very rich bibliography of over 2000 references.

M. T. ABOU-SALEH, *Senior Lecturer in Psychiatry, University of Liverpool*

The Unfinished Revolution in Italian Psychiatry: An Italian Perspective. Edited by RICHARD F. MOLLIKA. *International Journal of Mental Health*. New York: M. E. Sharpe 1985. Pp. 212. \$46.20

I was hoping that when I opened this book that it would bring a touch of colour to the stark black and white picture of Italian psychiatry that has been portrayed in the psychiatric literature over the past five years. This volume comprises two issues of the *International Journal of Mental Health*, and opens with Dr Mollica, who sets the scene well by explaining how Franco Basaglia's ideas developed from the political philosophy of Antonio Gramsci, who died in one of Mussolini's prisons in 1937. From this, one understands how politics and psychiatry in Italy are inextricably intertwined and why the Italian reform movement is so pre-occupied with the "second disease", the process whereby psychiatric patients became outcasts because of their segregation from society (Emarginazione). Basaglia's movement was not concerned with the primary treatment of psychiatric illness, only the form and setting in which it took place.

Unfortunately, after this promising start, we return to black and white accounts of the consequence of mental health reforms since Law 180 was passed in 1978. Thus Basaglia's widow (Franca), Jervis, Paparo and Bacigalupi, Carrino and Crepet all write as committed supporters of the reform and blame administrative incompetence or financial strictures in areas (e.g. the South of Italy) where the reform has limited or no benefit. Cassano, Mauri and Petracca, Hochmann, Jones and Poletti all oppose the reform and predictably find evidence to support their views. The most colourful contribution comes from Mario Tobino, who is both novelist and a psychiatrist, and who writes eloquently about the "foul wind" that has created chaos in Italian psychiatry.

But the colour comes from his literary style, not from the quality or information that the psychiatrist needs in judging the Italian reform. If this book was a tankard of beer it would be unfit for sale, because its contents are 80% "head" and only 20% beer. Most of the beer comes from our own Douglas Bennett, who is the only contributor who confines comment to the interpretation of data. He describes the changes that took place in the psychiatric services of Trieste between 1968 and 1978. The number of patients was reduced from 1260 to 366 and this was achieved without any significant change in staffing numbers. Although a great deal of information is missing about these patients one cannot help coming to the conclusion that for the typical psychiatric patient in Trieste the ideas that lay behind the reform of 1978 have been of benefit.

As for the rest of Italy, the "unfinished revolution" referred to in the title has an even less finished perspective. Psychiatrists there who are genuinely committed to improving psychiatric services find at least something of value in

the reform and those whose work is confined to hospital or private practice continue to criticise. Law 180 has confirmed the existence of three other laws; (1) good psychiatry cannot be created by legislation, (2) community psychiatry cannot be carried out without community resources, and (3) rhetoric is no substitute for data in the evaluation of psychiatric services. This book represents the opening speeches of prosecution and defence in the "Case of Italian Psychiatry". The evidence has yet to be presented.

PETER TYRER, *Consultant Psychiatrist,
Mapperley Hospital, Nottingham*

Metal Ions in Neurology and Psychiatry. Edited by SABIT GRAY, JOSEPH HARRIS, BENG T. HO. New York. ALAN R. LISS. 1985. Pp. 409. £72 00

This volume, which is the fifteenth in the series *Neurology and Neurobiology* has sought to highlight the role of metal ions in the field of neurology and psychiatry.

Recent advances in the chemical and pharmacological fields have increased our ability to measure and study the role of metal ions in various biological situations, thereby increasing our understanding of their role in human health and disease.

The contributors are all eminent scientists in their fields. The coverage is wide, though frequently lacking in depth. The quality and style of presentation also are inconsistent. For example, there is one chapter with over two hundred references and another with none. The chapters are organised on the functional aspects of metal ions so that a clinician who wanted to study the role of metal ions in, say, psychosis may need a careful compilation of pieces of information from several chapters. There are a few excellent chapters of interest to the psychiatrist like 'Vanadium and Affective Disorders' by G. J. Naylor and 'The Problem of Lithium Mechanisms' by J. L. Crammer. These apart, information of an immediate interest to a psychiatrist is contained with a varying proportion in the other chapters.

There are glaring omissions like the work of Carl Pfeiffer on the role of zinc and copper in schizophrenics, however much others may consider this as controversial.

These criticisms apart, the book has a wealth of information, more appealing perhaps to neurologists and pharmacologists. The editors have done well with a difficult task by bringing together a wide range of topics. They have succeeded in their declared interest of 'spotlighting current developments' and 'attempting to bridge the gap between clinical and fundamental approaches'. Their only worry should be, would that be sufficient to make a reader dip into his pocket to find the cover price of £72?

D. P. SRINIVASAN, *Consultant Psychiatrist,
Garlands Hospital, Carlisle*

Love and Tradition: Marriage between Jews and Christians. By EGON MAYER. New York: Plenum 1985. Pp. 311. \$17.95.

Egon Mayer is Professor of Sociology at Brookland College and also President of the Association for the Sociological

study of Jewry. The book is based on a survey of 450 intermarried couples, and attempts to describe what happens when an American Jew marries a Christian. It looks at how they approach their differences in religious observance, family life, and the customs surrounding births, deaths, marriages and rites of passage. It argues love does not conquer all, for tradition dies hard because it serves important human needs.

The book goes a long way towards dispelling the anxiety that intermarriages will eventually lead to the assimilation and therefore loss of Jewish culture and traditions. On the contrary, it seems that in a large percentage (33%) of intermarriages the Christian partner converts to Judaism, while only 10% of the Jewish partners convert to Christianity. In most marriages (43%) neither partner converts but they make an attempt to blend their two heritages and many Jewish customs and traditions are adopted and worked into the family life of the new couple.

This is not a book about marital therapy, nor is it about marital discord. It is a look from a sociological perspective at how the tension between love and tradition is resolved in marriages between Jews and Christians. As there is a tension in all marriages the book is of general interest. It is illustrated with lots of case studies. How applicable the findings are to the mixed marriages that are generated by our own multiracial society is of course open to question. The partners in many of these marriages often come from traditions that are much more difficult to bridge.

The book is worth a read to those interested in the problem of intermarriage and in the inevitable and complex interplay between love and tradition.

C. R. WHYTE, *Consultant Psychotherapist,
Humberstone Grange Clinic, Leicester*

Crisis Intervention - Theory and Methodology. By DONNA C. AGUILERA and JANICE M. MESSICK. Oxford: Blackwell Scientific Publications. 1986. Pp. 253. £14.50.

This small volume has been very popular amongst workers in crisis intervention settings since it was first published in 1970. It is now in its 5th edition, and there are some important changes both in style and content. Previous editions, have, in my view, been only of limited value to psychiatrists and have been written principally for other workers on teams. They have also been stronger on the practical applications of crisis intervention than on theoretical and academic aspects of the subject.

The authors (originally nurses) state in the preface to this edition that "it was not our intent in the previous editions of this textbook to imply that crisis intervention was limited only to one profession", and it is clear that this has been a common criticism. They have responded to this by adding some sections and enlarging others, and usefully by changing the style from a somewhat annoying and patronising second person to the more usual third person. In addition, the references are now at the end of each chapter and are extremely comprehensive.

This book is about 50% longer than before and most of this is taken up with an expansion of the section on dealing with crises.

The authors present a new model for conceptualising the problem in a diagrammatic form, which may be useful as a framework for some and is certainly simple and rational in its approach. The case histories, as always, are presented in a lively and sympathetic way are the strength of the work. The process of intervention is clearly explained and both the practical results and theoretical perspective are discussed.

There are two new chapters—one dealing with 'burn-out'—probably an essential component of any forward-looking book of the eighties—and one discussing socio-cultural influences on therapy which exclusively deals with cultural patterns in the USA and so is of limited value to a British readership.

As a basic introduction to crisis intervention for relatively inexperienced workers from many disciplines, this work is good value. It remains, however, a basic and superficial work and will not be very helpful to anyone with experience in the field.

GILLIAN WALDRON, *Consultant Psychiatrist,
Tower Hamlets Health Authority, London*

Diagnostic Interviewing. Edited by MICHEL HERSEN and SAMUEL M. TURNER. New York. Plenum Press. 1985. Pp. 365. \$37.50.

Ordinarily, diagnostic cookbooks in psychiatry, particularly if centering around a highly formulaic system such as the DSM-III, tend to be dull and boring. This volume, in which a group of American psychiatrists and psychologists put together the theory and practice of diagnostic interviewing, is an exception. The book is divided into three parts. The first part covers basic interviewing techniques and mental status examination. The rest of the book is devoted to the application of these principles to the major psychiatric disorders and special populations such as children and the elderly. Each chapter provides a DSM-II oriented description of the condition in question, followed by guidelines on how to collect and organise the necessary information to arrive at a diagnosis. The contents of the book are clearly and systematically presented.

The main strength of the book lies in the richness of clinical experience portrayed. The contributors share, with the reader, the "special strategies" of interviewing that they have developed in their clinical practice, and illustrate the do's and don'ts of the diagnostic process by suitable case vignettes. Though the presentations are uniformly good, the chapters on Affective Disorders (Van Valkenberg and Akiskal), Personality Disorders (Soloff), and Psychophysiological Disorders (Ward and Chesney) deserve special mention. While most chapters offer an eclectic, "medical model" approach to diagnosis, some contributors, notably Dupree and Patterson (assessing the elderly) present an unashamedly behavioural approach to assessment (not diagnostic) interviewing.

The book is missing in some areas. Neuroses, except anxiety, receive scant mention, there is no section on organic mental disorders, and the assessment of the suicidal and the dangerous mentally ill is hardly discussed. The book is technically well produced, but there are occasional errors.

The editors' stated aim is to provide a "how to do it" manual for beginning practitioners. This purpose is served

eminently by the book in its country of origin. For a novice trainee in Britain where clinical, particularly diagnostic practice is often very different, the contrast reflected in this book may be confusing. For the experienced clinician, however, such a refreshing contrast could be of great interest, and could help to sharpen his diagnostic tools. This book deserves a firm place in all psychiatric libraries.

M. S. KESHAVAN, *Assistant Professor in Psychiatry,
Wayne State University, Detroit*

Social Controls and the Medical Profession. Edited by JUDITH P. SWAZEY and STEPHEN R. SCHER. London: Eurospan Group of Publishers. 1985. Pp. 268. £27.50.

This book consists of a number of papers given at a series of conferences held between 1980 and 1982 as part of the Project on Social Controls and the Medical Profession established by a body known as Medicine in the Public Interest Inc. Little information is given about this interesting organisation beyond telling the reader that it is involved in studying current issues relating to medicine and science in the United States. The project was set up "in response to a perceived need to better define and analyse the governance of physicians as professionals" and, as one might expect from such a large topic, the contributions cover an enormous range from moral philosophy to an engaging piece entitled 'Laying down the scalpel: reflections on competence in a surgeon's career' by the Clinical Professor of Surgery Emeritus at Harvard. There are also papers on becoming a lawyer and on competence and impairment in the clergy which might, at first glance, seem out of place but, in fact, provide an interesting comparative element.

Competence and impairment in the medical profession seems to be the major theme of the book and many of the papers will be of interest to those involved in, and observing, this aspect of medical practice in the United Kingdom. The paper on impaired physician committees (IPC's) by Professor Ruddick of the Department of Philosophy at New York University entitled "Tough Love", Physician Advocacy and Moral Diffidence: Philosophical Reflections is of particular interest even though written in the context of American medicine. There is additionally a 34 page bibliography on impaired professionals and medical competence which will be of benefit to those wishing to pursue these topics. All in all this is an interesting book about certain aspects of medical practice in the United States. Much of what is written cannot be transferred to the British scene in total but may represent signs of things to come.

BILL MORGAN, *Lecturer, Department of Social Policy,
Newcastle University*

Clinical Neurology for Psychiatrists. 2nd Edition. By DAVID M. KAUFMAN. Orlando, Florida: Grune & Stratton. 1985. Pp. 431. \$44.50.

What is distinctive about a neurology text-book directed specifically at psychiatrists? Taking this one as the paradigm it means a beautifully-produced, clearly-written comprehensive neurological text enlivened by skilful and

informative line drawings. More attention is perhaps devoted to the differentiation of psychogenic disorders and the causes of dementia than in the average neurological text-book and readers are instructed to prepare formulations rather than make diagnoses but few other concessions to psychiatrists are discernible.

The contents are in two parts. Part 1 contains six chapters that cover classical anatomical neurology including peripheral nerve and muscle disorders. Particularly useful is the introductory chapter entitled 'First Encounter with a Patient' which provides helpful advice on structuring the interview and examination. The chapter on psychogenic disorders wisely advocates a sceptical approach to the diagnosis of hysteria and warns of the frequent concurrence of organic and psychogenic dysfunction in the same patient.

Part 2 covers major neurological symptoms including headache, seizures, pain, visual disturbance, aphasia and agnosia, sleep disorders, intellectual deterioration and sexual dysfunction as well as specific disorders such as multiple sclerosis, congenital abnormalities, cerebrovascular disease and brain tumour. Topicality is demonstrated by the inclusion of a section on AIDS and an illustrated chapter on investigative techniques including computerised scanning, positron emission tomography and nuclear magnetic resonance.

There are few aspects to criticise. The author is sceptical about epileptic psychoses and the statement "brain tumours rarely occur in young and middle-aged adults" is misleading. The fifty or so questions and answers at the end of each chapter and the 275 at the end of the book, although a useful aid to learning and revision, do materially inflate the size and presumably the price of the book.

Overall, however, this book is a pleasure to read and would benefit candidates for the MRCP as much as the MRCPsych. It can be recommended to clinical tutors as suitable library material.

K. DAVISON, *Consultant Psychiatrist and Lecturer,
University of Newcastle-upon-Tyne*

Psychological Applications in Psychiatry. Edited by
BRENDAN P. BRADLEY and CHRIS THOMPSON. Chichester:
John Wiley and Sons Ltd. 1985. Pp. 247. £19.50.

The editors of this volume have asked contributors to describe psychological approaches to understanding and treating disorders which correspond to psychiatric conditions and to base their discussion on research findings. The chapters cover obsessional-compulsive disorders, anxiety states, depression, schizophrenia, drug and alcohol dependence, neuropsychology, childhood disorders, psychogeriatrics, rehabilitation, and assessment.

The contributors provide well edited, up-to-date reviews. For such a concise volume it is surprisingly comprehensive and it serves as an excellent introduction to both psychiatry and clinical psychology.

Certain themes and trends predominate throughout the book. For example in his excellent chapter describing anxiety states Mathews argues that these disorders should be viewed as emerging from biophysical, psychosocial and cognitive-behavioural chains of events. Consequently, interpretation and treatment should take account of all

these factors or processes in a way that compliments or even replaces an emphasis on diagnostic categories and a one dimensional, medical approach. Similarly, in his description of the models of drug and alcohol dependence and his summary of treatment approaches, Gossop is highly critical of traditional views and methods. In their place he favours an alternative model using relapse prevention procedures in the form of cognitive-behavioural self-control skill training. The orientation adopted by Mathews and Gossop is echoed by Hemsley in his chapter on schizophrenia. He too concentrates on the importance of assessing the psychological and environmental factors using a functional analysis. Furthermore, he describes how among research and treatment possibilities one of the most interesting, exciting and promising newer approaches involves modifying cognitive and behavioural impairment via training in coping strategies. According to Powell a reorientation of this sort is also occurring in the field of neuropsychology. He describes a change in the role of the neuropsychologist from offering a diagnosis to that of providing an assessment of real life functioning in order to initiate management programmes and remedial training, for example using memory training for amnesics and biofeedback to reduce epileptic convulsions.

This book provides a real sense of the major concerns of clinical psychology and psychiatry in the 1980s. Very highly recommended.

PETER BUTCHER, *Principal Clinical Psychologist,
The London Hospital, Whitechapel, London*

Psychiatry: The State of the Art. Volume 7 - Epidemiology and Community Psychiatry. Edited by P. PICHOT, P. BERNER, R. WOLF and K. THAU. New York: Plenum Press. Pp. 693. £75.00.

Conscientious attendance at large academic conferences is hard work - the range of subjects is wide, the time given to each often short, and what appears in prospect, to be a deliciously varied menu all too often turns out to be a rapid procession of dishes which are all sampled but none really enjoyed before the next flavour appears. Proceedings of such conferences can produce the same effect as a jaded palate, without the pleasure of the social intercourse available at the live event.

The VII World Congress of Psychiatry, held in Vienna in 1983, has produced a series of 8 large volumes, of which this is the seventh. The compilation of all the contributions, from plenary sessions to poster presentations, into a coherent whole, has been a mammoth task of editorship, which has not, at least in this volume, been entirely successful. Perhaps it is by nature a somewhat 'catch-all' volume, but there is not a great deal of epidemiology in the work, which largely concentrates on community psychiatric issues. Some sections might have been placed with advantage with parts of other volumes, for example the papers under 'General Hospital Psychiatry' with the 'Psychosomatic Medicine' section in Volume IV. Similarly, some titles seem to have no particular relevance to social and community issues - the section on antidepressants in particular, which contains two or three papers entirely concentrating on psychopharmacology.

The most interesting sections are those on mental health services planning and delivery, where I found papers by Goldberg and Wing to be particularly helpful reviews. The most coherent and discrete section considers ways of helping the family cope with schizophrenia, and this contains some interesting international research findings which taken as a whole may truly reflect 'the state of the art' for this topic.

It is an opportunity to read of work done by a wider international authorship than that usually brought together in one volume, but in general the result is unsatisfactory. There are 103 papers in 18 sometimes arbitrary sections—some of the papers are reviews, some preliminary reports of research projects—the standard of English is immensely variable, the typesetting and reference style inconsistent. In conclusion, I would not think that many people would find enough original material presented in sufficient depth to justify its high price.

GILLIAN WALDRON, *Consultant Psychiatrist,
Tower Hamlets Health Authority, London*

Depressive States and Their Treatment. Edited by VAMIK VOLKAN. New York: Jason Aronson. 1985. Pp. 456. \$40.00.

This book, edited by Vamik Volkan, Professor of Psychiatry and Training Analyst aims to bring together the psychodynamic and psychobiological views of depression. In so doing, the contributions demonstrate the interplay of environmental stresses; psychodynamic factors; genetic, endocrine and biochemical factors in the causation of depression. Though each author offers some interpretation of the interplay, they do so from their own particular focus. Volkan rationalises these by dividing the books into five parts: Basic Concepts: Mourning and Depression in the Life-Cycle: Life Situations: Psychotherapy: Somatic Issues.

The basic idea of the book works quite well and each part may be read in its own right. This is with the exception of Part III on Life Situations which seems incomplete and somewhat contrived in comparison with the others. Basic Concepts provides introductory text, starting as it does from Freud's 'Mourning and Melancholia'. D Wilfred Abse offers two illuminating chapters examining depression from depth psychology. The next part on Life-Cycle works best when it focuses on early childhood experiences as precursors to later adult depression.

The part on psychotherapy confirmed by fears; that everyone finds depressives a demanding and constantly unrewarding group of patients with whom to work. Volkan gives us a concise exposition of his re-grief therapy, but perhaps the most imaginative chapter is by Sheldon Heath, warning us of the risk we all take of becoming a container for our patients' depression.

The final part of the book offers excellent reviews on the psychobiology of depression and its somatic treatment. However, by way of contrast, Morewitz warns that in

primary health care depression may be disguised by somatic presentation. As Morewitz notes the doctor has a tendency to see the patient as a body/mind split and as a whole this book goes a long way towards integrating this split as regards depression.

ALAN PRODGERS, *Senior Psychotherapist,
The Red House (Psychotherapy Services),
Salford Area Health Authority*

Handbook of Psychiatry 8th edition, ROBERT PRIEST and JARROLD WOOLFSON. London: William Heinemann Medical Books. 1986. Pp. 211. £7.95.

This is the 8th edition of a popular standard undergraduate textbook which was originally Minski's *Handbook of Psychiatry for Students and Nurses*. Despite several facelifts, or perhaps because of them, it remains appropriate both for undergraduate students of medicine and for nurses.

The book was last revised in 1979 and the two authors have made a number of changes for this 8th edition. Minski's name has been dropped and the book has an attractive new jacket design. The chief merit of the book in previous editions has always been its simplicity and clarity. Keywords are picked out in bold text and most of the difficult controversial areas of psychiatry are avoided or reduced to their noncontroversial essentials. The 8th edition retains these features.

The chapter on Psychiatry and the Law has been completely rewritten by John Hamilton to take account of the changes caused by the new Mental Health Act. There is also a new chapter on psychosomatic disorders in which the concept is illustrated by three eating disorders, anorexia nervosa, bulimica nervosa and obesity. A section of defence mechanisms has been added to the introduction and a short section on psychiatric disorders of pregnancy and the puerperium. A brief section on adolescence has been added to the child psychiatry chapter.

The main changes have been in the treatment chapter. Sections on barbiturates, other older hypnotics, insulin-coma and modified insulin therapy have all been dropped at last. Some of the newer antidepressants have been added, although it is likely that at least one of them will have to be precipitately dropped by the next edition. The substituted benzamides have been added as a class of neuroleptic and the classification of antipsychotic drugs has been clarified. The authors have also added a section on care of the dying patient to the psychotherapy chapter.

In summary, this 8th edition of a popular textbook, has brought the text up to date and it seems that as the authors gain confidence in their ability to simplify without distortion they are expanding the subject matter into more controversial areas.

THE BRITISH JOURNAL OF PSYCHIATRY

November 1986

Vol 149

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrist

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG*.

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489–1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper**.

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full**. Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in italic and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971)' showed that . . .'

DURKHEIM, E. (1897) *Le Suicide*. Paris. Translated (1952) as *Suicide: A Study in Sociology*, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. *British Journal of Psychiatry*, **124**, 352–358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) *Education, Health and Behaviour*. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In *Pathology and Treatment of Sexual Deviation* (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80–110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180–210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

© 1986 THE ROYAL COLLEGE OF PSYCHIATRISTS

The University
of
British Columbia

DEPARTMENT OF PSYCHIATRY HEAD OF DIVISION OF CHILD PSYCHIATRY

Applications are invited for the position of Head of the Division of Child Psychiatry. The Division consists of 4 full-time and 14 part-time faculty, who work and teach at three sites: Vancouver General Hospital (outpatients and a 10-bed adolescent unit), B.C.'s Children's Hospital (out-patients, liaison service and a 10-bed unit for children) and the Health Sciences Centre Psychiatric Unit (child and family outpatients). The Division has places for residents to do their mandatory six months of child psychiatry, or two years to specialize in child psychiatry. The Division is also responsible for undergraduate medical student instruction.

The new Head would be responsible for planning new services, coordinating the teaching program and promoting research. As the Division is on the point of new development this would be an exciting and rewarding post for an energetic administrator/clinician/teacher/researcher. Appointment to this position would be at the Professor or Associate Professor level and is subject to final budgetary approval. Applicants should be eligible for medical licensure in British Columbia. Salary and rank will be in accordance with existing academic scales for The University of British Columbia.

In accordance with Canadian immigration requirements, priority will be given to Canadian citizens and permanent residents of Canada.

Applications, including c.v., and names and addresses of three referees should be sent to: James E. Miles, M.D., F.R.C.P.(C), Professor and Head, Department of Psychiatry, The University of British Columbia Health Sciences Centre Hospital, 2211 Westbrook Mall, Vancouver, B.C. V6T 2B5.

VISITING PSYCHIATRIST

HM PRISON, BRIXTON, LONDON SW2 5XF

The Prison Medical Service is responsible for the health, mental and physical, of all inmates in Prison Service establishments. The medical staff work in collaboration with visiting specialists. An opportunity exists for a visiting psychiatrist to make an important contribution to the medical services at HM Prison Brixton, which is a local prison presently accommodating 997 adult males.

Applications are invited from fully registered medical practitioners of consultant status. The requirement is for two or three sessions a week at present. The work involves mainly the psychiatric assessment of inmates referred by the Medical Officer and advising on treatment.

Applicants should live within reasonable travelling distance of the prison.

The fee payable per session (of between 2½ and 3½ hours) is £61.50. Certain travelling expenses are payable in addition.

Further information can be obtained from the Principal Medical Officer, HM Prison Brixton, telephone 01 674 9811.

Requests for a form of application, which should be completed and returned within 21 days of this announcement appearing, should be addressed to:

Recruitment Section, Room 402—IR, Home Office, Cleland House, Page Street, LONDON SW1P 4LN

The Home Office is an equal opportunities employer.

When there seems to be no way out.

Ticehurst House was established as a psychiatric clinic more than 200 years ago. Today it retains its position at the forefront of psychiatric care.

The reputation of Ticehurst House stems from the comprehensive service it offers to patients and to the medical and psychiatric professions.

The psychiatric team at Ticehurst House offers a full spectrum of treatments in the care of short and long term patients and specialises in the active care of short term patients, the treatment of alcoholics and the assessment and treatment of psychogeriatric patients.

The hospital responds promptly to requests for out-patient consultation and admission of patients. There are excellent liaison procedures between Ticehurst House and outside Consultants and G.P.s.

The special facilities at Ticehurst House include a psychogeriatric assessment unit, the Newington Alcohol Treatment Unit and facilities for day care patients.

Within the grounds of the hospital Highlands Lodge offers high quality accommodation for low dependency patients under the care of Consultants and experienced nursing staff.

Ticehurst House enjoys an excellent reputation for its cuisine. Bedrooms are spacious and equipped with nurse-call systems.

It is easily accessible by both road and rail, being close to Wadhurst in Sussex (70 minutes from Charing Cross), and stands in forty-eight acres of delightful gardens and grounds.

For further information write or telephone The Medical Director, Ticehurst House, Ticehurst, Near Wadhurst, Sussex TN5 7HU. Telephone (0580) 200391.

NEW Videotapes from TAVISTOCK

Seminars in Behavioural Psychotherapy

Presented by **DAVID GOLDBERG**

A set of two tapes illustrating the work of three behavioural psychotherapists, John Cobb, Shirley Mercer, and Nagy Bishay. Between them they provide a set of four suggested teaching seminars. They include role-plays with commentaries, discussion points, and exercises which have been successfully used in the Department of Psychiatry and which can be easily adapted by course teachers for group or individual viewing.

Part I and Part II 40-60 minutes colour notes

VHS Part I £85.00 + £12.75 VAT = £97.75

Part II £85.00 + £12.75 VAT = £97.75

Parts I and II £145.00 + £21.75 VAT = £166.75

Problem based interviewing in General Practice

Presented by **ART LESSER**

This tape was made at Manchester by the Canadian psychiatrist Art Lesser to illustrate his work in teaching interviewing skills to trainee general practitioners. The aim is to help students identify and treat underlying problems which cause patients to come to their surgeries and which may be masked by an apparently straightforward complaint. He suggests how to look for verbal and visual clues and presents a model for problem sensing, detection, description, assessment, treatment, and evaluation.

Annotation

Long-term Psychiatric Patients in the Community

K. JONES, M. ROBINSON and M. GOLIGHTLEY

The reduction of mental hospital populations in Britain and the United States has generated a considerable amount of literature on policy, but detailed studies of the effects on patients and the conditions under which they live after discharge are rare. In the United States, a National Institute of Mental Health review of the literature commented that "the question of what actually happens to patients who leave mental hospitals and re-enter the community is largely unanswered" (Bachrach, 1976).

In Britain, there have been three main research approaches:

- (a) computerised case-register studies based on the Camberwell model (Wing & Hailey, 1972), of which Cheadle *et al* (1978), Howat & Kontny (1982) and Sturt (1984) are recent examples
- (b) studies of patient groups from particular agencies, such as day hospitals (Milne, 1984), assessment units (Eagles & Gilleard, 1984), district general hospital units (Gibbons *et al*, 1984) or ward support schemes (Mitchell & Birley, 1983)
- (c) studies of the input of specific professional groups, such as general practitioners (GPs) (Shepherd, 1976), social workers (Fisher *et al*, 1984), or community psychiatric nurses (Paykel *et al*, 1982).

All three types of study are service-based. They provide a valuable approach to the evaluation of services, but give only limited information on what the patients in the ill-defined area called 'the community' actually experience. Some patients may be receiving a complex of services from different agencies, while others receive few or no services. Detailed tracer studies which take the patient rather than the service as a focus are needed. Who helps? Who fails to help? How do hospital-based and GP services fit together with social work, private, and informal (family care) services? The move from hospital-based to community-based services involves a sizeable re-

definition of patients' problems from 'medical' to 'social'. Does it work in practice?

Studies involving interviewing ex-patients and their relatives or other carers are difficult, and therefore rare. Patients move, and are sometimes difficult to trace, so there is a risk of attrition in the sample. Some prefer to forget their time in hospital, and do not wish to be interviewed; some, in continuing distress or confusion, may misunderstand the purpose of the exercise, and require sensitive handling; and some may not give coherent replies. The study of non-medical services is new to most medical research workers. The few recent and relevant follow-up studies (McCreadie, 1982; Sadavoy & Reiman-Sheldon, 1983; Johnstone *et al*, 1984) have all been concerned with symptomatology rather than with the quality or mix of care. An opportunity to carry out a study for York Health District on patients discharged from the three York mental hospitals (Clifton, Naburn, and Bootham Park) into the York area was therefore welcomed as a pilot project. A full report on this project is available (Jones, 1985).

The two samples chosen for the follow-up consisted of:

- (a) the long-stay group: all patients who had been continuously in hospital for over one year, and who were discharged in the period 1 April 1982 to 31 March 1984 ($n=50$)
- (b) the elderly confused group: 100 patients selected randomly from a total of 203 aged 65 and over with a diagnosis of senile dementia (ICD categories 290.0-290.9, World Health Organization, 1978) and discharged during the same period.

Perhaps the most important finding is that the project was viable. All but two of the patients (elderly confused who had left the district) were traced, and no major objections to the research procedure were encountered. The project was approved by the local Medical Ethical Committee. In all cases, the Responsible Medical Officer agreed to the follow-up.

Patients' general practitioners were consulted, and in only four cases did they think that an interview would be too stressful for the patient: these cases were removed from the sample. The interviewers (two senior social workers, two college lecturers, and a psychologist) were instructed to withdraw at once if either patients or their carers had any objection to the interview procedure: this occurred in only 12 cases. Most were happy to talk, and many seemed to find a friendly visit helpful. The only complaint came from an ex-patient who had *not* been included in the sample.

In-depth interviews, based on checklists, lasted from one to three hours. The interviewers completed both the checklist and a detailed case study for each patient. The case studies produced a wealth of data from which it would be possible to derive a substantially refined research instrument for future studies, with an improved computer database.

Results

The long-stay sample

Patients interviewed were evenly divided between men and women, and covered a wide age-range—from 24 to 82. The length of stay in hospital varied from just over a year to 43 years. Over half had a diagnosis of schizophrenia. The older patients tended to have one admission and a long hospital stay, while the younger ones had multiple admissions and shorter stays. At the time of interview, only five were living in their own homes or a family home. The rest were scattered between local authority homes or hostels, private registered homes, group flats, and lodgings. None were in prison; one was sleeping rough, and two were back in mental hospital. Placements had been made with great care (York has a homefinder who believes in 'intuitive matching' between the patient and the setting—a highly individual process) and most patients appeared to have made a reasonable adjustment.

The elderly confused sample

Of this group of 100, 35 had died before the time of interview, and 23 were back in hospital. Three of these patients had been discharged in their nineties. Only ten of the sample were found to be living in their own homes or a family home. Others had been discharged to local authority or private registered homes, or to sheltered housing. The elderly confused in their own homes were much less well-supported than the younger long-stay patients. Where there was only a mild degree of senile dementia, the family was

large enough to spread the burden of care, and there was enough money to cushion the situation, the problems were manageable; but where the mental condition was severe and disruptive, there were physical complications such as blindness or incontinence, the burden of care fell exclusively on one relative (usually a husband or wife, also old and often in failing health), and the financial resources were strained, the situation could be nearly intolerable. Neighbours offered little help, and friends were scarce. Although the health and social services were initially involved, visits tended to tail off after a few months. The expectation of the current model of community care is that patients will improve after discharge from hospital; senile dementia does not fit the pattern.

Hospital discharge plans

These were faithfully drawn up, but tended to be unrealistic. They made no mention of where the patient was expected to live (presumably on the assumption that they would all return to their own homes). They did not list GP or out-patient clinic services, and there was a marked under-use of social services. Most discharge plans recommended the use of only one community-based service, although patients in fact needed several in combination. The situation after discharge was often unstable, and the need for support more complex than the discharge plan data suggested. We concluded that what was needed was not a 'discharge plan' (which clears a hospital bed), but a community care plan which offers a possibility of stable living conditions with adequate support.

Success of placement

The patients in these samples did not bear out the gloomier prognostications of those who distrust care in the community—similar surveys in other areas might have less positive results. Of the total of 38 who died before the interviews took place, 35 died of natural causes (two elderly confused patients died as a result of falls, one in hospital and one in a home, and one long-stay patient committed suicide). But were the rest happier in or out of hospital? It is often taken as axiomatic that any kind of life 'in the community' is better than staying in a mental hospital; as the survey results indicate, however, patients go out to a variety of settings, and not all of them are necessarily beneficial.

Quality of life study

The research team attempted to devise a scale

sufficiently flexible to cover both life in hospital and life in the variety of settings to which patients were discharged, and the matching of conditions for each patient in both settings. While many quality-of-life scales have been constructed for different purposes, the combination of hard and soft data poses severe problems of measurement, and there are difficulties in weighing individual items. Scales based on some concept of 'normal living in the community' are open to the objection that we have little idea what is 'normal' for severely handicapped or disturbed people. After studying existing scales, the team came to the conclusion that the construction of a new and simplified scale was the only useful approach. The York Scale is based on Maslow's (1943) hierarchy of human needs. It measures four groups of needs (survival, safety/security, purpose, and independence) on three dimensions: needs met, needs partly met, and needs unmet. The scale needs further development, but it was found that

- (a) patients' own homes scored well on choice and autonomy, but not on health care, personal care, activities, and companionship
- (b) local authority homes provided personal care, but scored poorly on health care, privacy, and activities
- (c) private homes (usually run by psychiatric nurses) provided good personal and health care and activities, but were often cramped and lacking in facilities
- (d) mental hospital wards provided best for basic survival needs, health care, and activities, but not for personal choice, privacy, or autonomy. Nor did they provide for stability, since patients might be moved to another ward or discharged at any time.

Conclusions

The findings of the survey should be treated with caution, since the samples were restricted in scope and comparatively small. However, they provide pointers for practice and for future research.

Most of these patients were still living in fairly institutional surroundings. Whether they were better or worse off than in hospital depends on a variety of factors relating to the individual patient and the individual setting – there is no clear general answer indicating the superiority of 'hospital care' or 'community care'.

The questionnaire had been constructed in the expectation that most of the patients in the samples would be found in their own homes, and that if they

were fit for discharge, they would be able to sustain an interview. Both of these assumptions were disproved. Only one in ten of the patients were in their own homes, and few were capable of answering questions. Most of the information came from people such as relatives, officers in charge of homes, landladies, hostel wardens, and hospital staff. Often even professional staff were uncertain in their replies – they could not remember the names of GPs, or say when a visitor had last called, or whether patients had relatives. Patients who are incoherent, or passive and undemanding, do not seem to inspire good record-keeping, although they may need it more than most.

Even in York, a fairly compact city, the study revealed the great complexity of care in the community: the difficulties which health and social services have in working together when they have different legislative bases, different working styles, different patient groupings, different planning and budgeting cycles, and different professional backgrounds; the problems of the small voluntary societies in trying to work with the statutory 'giants'; the isolated pockets of private care, and the difficulties of co-ordinating all these services with GP care. The 90 patients interviewed – all living within a limited area – had 67 different GPs. Repeated official exhortations to collaboration and co-operation (Department of Health and Social Security, 1975, 1978, 1981) will be of little effect unless attention is given to finding administrative solutions which provide a mix of services where needed.

Modest research projects of this kind, which can be of practical and immediate use to the psychiatric services, may be of particular value when a major policy shift is being implemented. They need to be tightly scheduled, and to provide quick returns. The survey reported here was planned, executed, and reported back to York Health District within twelve months. It took place in the context of rapidly-developing services; in the past year, two additional consultant posts have been established, with specific responsibilities to develop after-care services for younger patients with chronic handicaps, and for the elderly confused; numbers of community psychiatric nurses have been increased; an 'at risk' register has been set up; funds have been released to social services to provide for collaboratively planned day care; community mental health teams are being formed to work with GPs in designated localities; and plans are well ahead for the provision of four community resource centres and eight community units for the elderly. Small-scale in-depth research can help to maintain the momentum of change, and provide rapid feedback on groups in special need.

Lithium Treatment: A Refresher Course*

M. SCHOU

Updated guidelines are presented for the safe and effective use of lithium; covering indications, treatment management, duration of prophylactic treatment, side-effects and their prevention, overdosage, interactions, and contraindications. Alternatives to lithium and patient-doctor co-operation are discussed.

Many patients are given lithium treatment for long periods of time, and questions may arise for patient and doctor before and during treatment. This paper is an attempt to provide answers to questions often asked; answers are also proposed for questions which may not be asked but should be. The didactic aim and space limitations have necessitated a certain bluntness of statement. The opinions presented are the author's own; others may hold different and equally valid views.

Indications

Although given for some somatic diseases (neutropenia, cluster headache), lithium is used primarily for the treatment of psychiatric illness.

Mania

As an antimanic treatment, lithium preceded the neuroleptic drugs by about five years, and its efficacy has been firmly established. Lithium nevertheless appears to be used rather sparsely on this indication, and one wonders whether the preference for neuroleptics may not to some extent stem from impatience on the part of staff and doctors. The full antimanic effect of lithium develops gradually over about a week. Acute or fulminant mania must therefore be treated with a quick-acting neuroleptic or with ECT, but in less fierce cases, lithium is preferable from the patients' point of view, because it induces less feeling of restraint.

In mania of strong intensity, it may be advantageous to start treatment with a neuroleptic drug in combination with lithium, and then to reduce the

dosage of the former over the following week, as lithium takes effect. Therapeutic intervention is rarely popular with manic patients, but avoidance of the hard-hitting neuroleptics may make treatment more acceptable.

Depression

Early clinical observations and trials failed to show antidepressant effects of lithium, but later studies, including some with placebo-treated controls, have revealed that lithium does in fact exert some therapeutic effect during a depressive episode. Depressions occurring as part of a bipolar illness may respond better than those with a unipolar course. The effect of lithium may set in later than that of the conventional antidepressants. There are at present few who use lithium as first choice antidepressant treatment, but in patients with a tendency to postdepressive hypomanic upswings, this therapy may merit consideration.

The antidepressant properties of lithium seem to be of value in a different setting. Several studies have shown rapid improvement when lithium was added to antidepressants in patients whose depression had been refractory to treatment with the latter drugs alone. Whether this is the case also for those depressions which tend to take a chronic course remains to be seen.

Recurrent manic-depressive illness

The prophylactic effect of lithium in manic-depressive illness is by now one of the best documented in psychiatric pharmacotherapy, and it must be considered a grave medical error not to offer prophylactic treatment with lithium (or one of its alternatives) to patients with frequent and severe recurrences.

*Based on a lecture given to the Royal College of Psychiatrists in January 1986

The following points are clinically relevant.

- (a) Prophylactic lithium treatment is equally effective in women and men and, provided appropriate dosage adjustments are made, in young and old.
- (b) In bipolar patients, the prophylactic action has been found better in some studies against depressive than against manic relapses. Other studies have shown the opposite. Most studies, however, indicate equal efficacy against the two types of relapse.
- (c) In some patients, the effect seems to be primarily a reduction of episode frequency, in others a reduction of episode intensity. In many patients the two are combined.
- (d) Patients with frequent episodes, more than 3–4 per year, may respond poorly to prophylactic treatment, but sometimes they respond excellently.
- (e) In some patients, the prophylactic action of lithium sets in gradually, so that the full effect is seen only after 6–12 months of treatment; relapses do occur during this period, but with gradually decreasing frequency and intensity. In other patients, no relapses are seen once lithium treatment has been started.
- (f) Lithium does not seem to lose its effect.
- (g) Lithium is not addictive.

The efficacy of lithium prophylaxis in unipolar illness has been the subject of debate, but dissent has been more of opinion than of evidence. A few reports have indicated that lithium is less effective in unipolar than in bipolar illness, but most studies show it equally effective in the two forms of the disease. It is perhaps significant that doubts about efficacy in unipolar illness have been raised primarily in the United States, where the concept of unipolar illness may be used more loosely than in Europe.

The question of when prophylactic treatment should be instituted has received different answers, and a general one may not exist. Early prophylactic trials were carried out on patients with two or more episodes within the last two years, but this criterion clearly excludes too many patients who might benefit from the treatment. Another suggested startpoint is when bipolar patients have suffered their third and when unipolar patients have suffered their fourth episode, and even this may be too late. Suicides often occur earlier. Individual factors must be taken into account, such as family and work situations, severity and duration of episodes, and response to conventional therapy. The decision about prophylactic treatment should be made jointly by the psychiatrist and the well-informed patient and spouse.

Aggressiveness

At an early stage, lithium was designated 'specific' for manic-depressive illness, because it acted on both the manic and the depressive manifestations of the disease and because it did not have the broad therapeutic spectrum of the neuroleptics. Lithium effects have nevertheless been clearly demonstrated also in psychopathological conditions which cannot (or can only by stretching the term) be called manic-depressive. Foremost among these is episodic pathological aggressiveness with explosive behaviour. Such effects have been seen in persons with unstable character disorder, in sociopathic prison inmates, in children, and in mentally retarded persons. In the last-mentioned, the antiaggressive action was apparent both when the aggression took the form of self-mutilation and when others were attacked. It is not clear whether the effect of lithium is exerted primarily on the aggressiveness itself or on the – often irregular – periodicity.

Documentation of lithium effects on periodic aggressiveness is so solid, based on double-blind as well as on single-blind studies with large numbers of treated subjects, that one would expect lithium to be used rather widely on this indication. That has not been the case, and a reason may be the prevailing general hesitation about administering drugs to children and to inmates in penal or ward institutions. It may be worth remembering, however, that those responding to lithium reported substantial subjective relief from their previously uncontrollable bouts of rage and violence.

Other

The evidence concerning lithium effects in schizoaffective illness and schizophrenia ranges from clearly negative results to highly gratifying treatment outcome. The latter concerns not only affective elements but also, according to some studies, schizophrenic core symptoms. The question requires further enquiry, but lithium treatment, alone or in combination with neuroleptics, may be worth consideration in patients where the psychopathology shows periodicity, regular or irregular.

Positive reports about lithium effects in alcoholism not secondary to recurrent affective illness are balanced by clearly negative studies. Uncontrolled trials have indicated lithium prevention or amelioration of premenstrual dysphoria, but placebo-controlled studies on larger patient groups have not.

Treatment management

Preparations and dosage pattern

It is of little importance whether lithium is taken in tablet form, in capsule form, or as a syrup. Nor is it of consequence whether one employs lithium carbonate, lithium citrate, lithium sulphate, or any other lithium salt, as long as the preparation used has constant release properties, and releases the full content of lithium during the passage through the gastrointestinal tract. Low or variable release involves risk of underdosage with relapses or overdosage with intoxication.

There has been discussion about the relative advantages of two treatment regimens: (a) one with a softly undulating course of the serum lithium concentration over 24 hours, as produced by administration of sustained-release lithium tablets or by the use of two or more daily doses, or both, and (b) one with higher peaks and lower troughs of the serum lithium curve, as produced by administration of conventional tablets once per day. The question has not been definitively resolved, and it is complex, because wanted effects and side-effects may respond differently to different treatment regimens, and different side-effects may not respond in the same manner. Comparisons between clinics have been carried out, but final answers can be obtained only through prospective within-clinic trials with random allocation of regimens.

Even though we have taken an active interest in the problem at our hospital, we do not at present plan such studies, because it is our impression that the general dosage level is much more important than the treatment regimen. About five years ago, we reduced dosages and serum levels by about 20%, from an average dose of 30 mmol/day to 24 mmol/day and from an average serum level of 0.85 mmol/l to 0.70 mmol/l. This has not led to any marked reduction in prophylactic efficacy, but a number of side-effects have fallen drastically in frequency and intensity. In many patients, side-effects have ceased to be a problem.

Dosage adjustment

Renal lithium clearance and sensitivity to lithium vary from one person to another, and individual dosage adjustment is necessary. Methods for predicting the maintenance dose from the serum lithium level 24 hours after a test dose have been devised. Alternatively, a stepwise procedure may be used: (a) administration of a low test dose—1 or 2 tablets daily—for one week; (b) determination of the serum

lithium concentration and adjustment of the dosage to produce a serum concentration between 0.5 and 0.8 mmol/l; (c) individual after-adjustment if necessary: increase on the occurrence of relapses, decrease in case of troublesome side-effects.

Laboratory monitoring

Laboratory tests before lithium treatment may include examination of the urine, serum creatinine and thyroid stimulating hormone (TSH), haemoglobin, sedimentation rate, blood pressure, electrocardiogram, and body weight. These should be supplemented by others if there is a medical history or suspicion of somatic illness.

During treatment, the serum lithium concentration should be determined once per week during the first weeks, and thereafter at longer intervals. The blood samples for serum lithium determination should be drawn in the morning, 11–13 h after the last intake of lithium. A serum concentration between 0.5 and 0.8 mmol/l is appropriate for most patients, but individual adjustment to levels outside this standard range may be necessary. Supplementary examinations, for example of serum creatinine and TSH, may provide extra safety, and suspicion of intoxication or complications requires additional laboratory control.

The frequency of the control visits is usually determined by clinical considerations. It is important for the co-operation between patient and doctor that they meet at intervals to discuss treatment progress, side-effects, and dosage adjustment, as well as possible social or personal problems associated with the illness and the treatment. The main importance of the laboratory visits may lie in the provision of a structured framework for these contacts. Intervals between routine checkups therefore depend on the patients' personality, intelligence, and educational level, the extent of information and instruction they have been given, the clinic routine, etc.

Recommendations given here deal with minimum requirements for laboratory monitoring under ordinary circumstances. However, sometimes such 'ordinary' circumstances are extraordinary. In developing countries, even strongly indicated lithium treatment may not be instituted because laboratory facilities are lacking, and in countries without a socialised health system, poor patients may be deprived of this treatment because they cannot afford the cost of regular laboratory examinations. In my opinion, it is not irresponsible to prescribe lithium treatment even without laboratory monitoring if the alternative is that no prophylactic therapy is given.

Duration of prophylactic lithium treatment

Statistical evidence indicates that the frequency of manic-depressive relapses tends to rise with increasing illness duration, and more rapidly in bipolar than in unipolar patients. It is therefore likely that a patient who is started on lithium owing to frequent episodes within recent years will also need lithium during years to come. It seems, however, psychologically important that psychiatrists avoid the blunt 'for life' statement to patients who start, or consider starting, lithium treatment. The question should be kept open for future discussion in the light of experience.

In some patients, subclinical 'reminders' reveal that the disease is still active underneath and that discontinuation of lithium is inadvisable. In other patients there are no signs of ongoing illness, and the patient's wish to try stopping lithium may become urgent. Discontinuation under strict supervision can in some instances be executed with impunity, but in most cases recurrences develop sooner or later, and the patient goes back on lithium, so much the wiser.

Lithium can usually be stopped abruptly without the appearance of withdrawal symptoms. In a few patients withdrawal is followed by anxiety; stepwise discontinuation and psychological support may be indicated. In some studies, the early appearance of relapses after discontinuation of lithium has suggested that rebound may occur. Other studies, including some with large patient groups and double-blind design, showed no evidence of rebound.

Side-effects

Psychological side-effects

In view of its striking effects on manic and depressive episodes of abnormal mood, lithium exerts remarkably little action on normal mental faculties. Most patients in long-term lithium treatment feel normal and function normally. There are patients who complain of impaired memory or reduced reaction speed, and although in some instances this may reflect deprivation of manic hyperacuity, there is reason to believe that lithium itself occasionally exerts such actions in sensitive persons. The same effects have been noted by normal subjects who took high lithium doses.

Lithium treatment counteracts not only manic and depressive episodes of abnormal mood; sometimes it also produces a more stable mood during the intervals between episodes. This is felt by some patients as a gain, providing less fluctuation and better self-control. Others miss their previous enthusiasm, and

feel that life under lithium has become less interesting and colourful.

The effect of lithium treatment on artistic productivity has been the subject of several investigations. The most extensive study reported that out of 24 manic-depressive artists in whom lithium treatment had brought the disease under control, six found that their creative power had diminished, six that it was unaltered, and twelve that they created more and in some instances also better when prevention of manic and depressive episodes permitted a more even working rhythm and better artistic discipline.

Lithium effects on mental functions are readily reversible, and disappear when lithium is discontinued.

Somatic side-effects

Some patients interrupt lithium treatment because they suffer troublesome somatic side-effects, but this is relatively rare when one uses the lower dosage and serum lithium ranges mentioned above. Proper attention should nevertheless be given to even trivial physical side-effects, because in long-term treatment, they may influence life quality significantly.

Many side-effects are more pronounced when the serum lithium level is high, and the principal remedy should be an attempt to use lower doses and serum levels. Fine adjustment in each patient is essential, and sometimes the reduction of serum lithium by 0.1–0.2 mmol/l may make all the difference to the patient's well-being.

Supplementary treatment of side-effects may include beta-blocking agents for lithium-induced tremor, and it seems that intake 'for the occasion', for example 10–20 mg of propranolol 30 minutes before the start of a meeting or the beginning of a party, is more effective and less liable to development of tolerance than continuous intake.

Lithium-induced hypothyroidism may be detected earlier by regular determinations of TSH than by clinical observation alone, and it should not go untreated. Administration of small doses of thyroxine, given concurrently with lithium, effectively lowers TSH, reduces the size of a goitre, and ameliorates the symptoms of hypothyroidism.

Morphological changes have been seen in the kidneys of patients given long-term lithium treatment, but the occurrence of similar changes in patients about to start, but not yet having started lithium treatment has raised doubts about their specificity. The findings nevertheless led to extensive studies of kidney function during lithium treatment, both transverse and longitudinal. They confirmed previous experience that lithium may induce lowering of

the renal concentrating ability by making the distal tubules refractory to the action of the antidiuretic hormone, and this may lead to development of polyuria and polydipsia. The studies have in addition documented that lithium treatment, even when given for many years, does not lead to progressive reduction of the glomerular filtration rate. No patient has died from lithium-induced renal insufficiency and terminal azotaemia.

If patients develop lowered renal concentrating ability, they should be instructed to respect feelings of thirst and to avoid situations involving risk of dehydration, but even a low maximum urine osmolality does not constitute grounds for discontinuing psychiatrically indicated and otherwise well tolerated lithium treatment. Administration of diuretics can lower the urine volume, but the procedure is dangerous; amiloride may be safer than other diuretics.

Weight gain may be a result of hypothyroidism, which should be treated, or it may be secondary to lithium-induced thirst, and the patients should then avoid quenching their thirst with calorie-rich drinks. Sometimes the weight gain has no explanation other than the lithium treatment itself. Restriction of calorie intake and increased exercise are appropriate remedies, but often difficult to implement.

Intoxication

The risk of long-term lithium treatment is development of intoxication which, if severe, may lead to death or to long-lasting cerebellar damage. It is important to note, however, that lithium intoxication does not occur capriciously and does not develop suddenly.

Some patients consume a large lithium dose by mistake or because they want to kill themselves. We should perhaps impress on our patients that lithium is neither an effective nor a pleasant self-destructive agent. More often, lithium intoxication is gradual and caused by a too low elimination rate. Usually, the renal lithium clearance is one-quarter of the creatinine clearance, and it falls when the glomerular filtration rate falls, for example as a consequence of kidney disease. However, occasionally the lithium clearance falls disproportionately; under circumstances of negative sodium and water balance. Risk situations during lithium treatment accordingly include physical disease with fever, heavy sweating, vomiting and diarrhoea, low-salt diet, drastic slimming, and treatment with diuretics. Fluid should be administered parenterally to patients in lithium treatment if they vomit massively, if they are uncon-

scious for many hours, and during the night before major operations with narcosis, when oral fluid intake is prohibited.

There are signs and symptoms which herald incipient poisoning, and if any of them becomes prominent, serum lithium should be checked to ascertain the condition. They include dullness, sleepiness, difficulty concentrating, muscle weakness or muscle twitches, unsteady gait, coarse hand tremor, indistinct speech, nausea, and diarrhoea,

Interactions

Interaction of lithium with particular situations is usually more important than interaction with other drugs. Lithium is excreted exclusively through the kidneys, and the lithium clearance is under most circumstances a constant fraction of the creatinine clearance. There is accordingly danger associated with circumstances which lead to a fall of the glomerular filtration rate, for example kidney disease or cardiac failure. There is also risk in situations where the renal lithium clearance falls independently of or more than the filtration rate, for example during dehydration or as a result of a negative sodium balance. Doctors should be aware of the special precautions and safety measures outlined above.

Adverse interaction with other drugs may be mediated through interference with renal lithium elimination. Diuretics are an important example: they are often sold as over-the-counter drugs and consumed without medical control, and several cases of lithium intoxication have ensued because the doctor failed to give an appropriate warning. Interaction with non-steroid antirheumatics such as indomethacin and phenylbutazone has also been seen, and although the underlying mechanism is not clear, interference with renal elimination is probably involved.

Lithium is often administered together with antidepressants or neuroleptics or both, and in most cases this does not present problems. Combination with antidepressants may sometimes lead to aggravation of hand tremor, and combination with large doses of neuroleptics, particularly haloperidol, has occasionally given rise to confusion and intoxication-like states. Combination with low doses of neuroleptics, e.g. haloperidol in doses lower than 20 mg/day, does not seem to present problems.

There does not seem to be interaction between lithium and anxiolytics, hypnotics, analgesics, vitamins, or contraceptive agents. Nor does lithium treatment interact with drugs against epilepsy, thrombosis, or diabetes. Lithium does not ordinarily change the effects of alcohol.

Contraindications

Since constant kidney function is a prerequisite for safe lithium treatment, lithium is contraindicated in patients who suffer from glomerulonephritis, severe pyelonephritis, or cardiac insufficiency. The glomerular filtration rate falls with advancing years, but as this is a gradual process that does not involve fluctuations, age as such is no contraindication against lithium: elderly persons merely require lower doses to achieve the same serum lithium levels. Patients undergoing maintenance haemodialysis have been given lithium safely, in some cases by adding lithium to the dialysis fluid.

Surgeons would be wise to discontinue lithium treatment some days before major operations which may interfere with fluid and electrolyte balance, but it is important that lithium administration is resumed when kidney function and electrolyte balance have become normal again.

Previous liver disease does not constitute a contraindication against lithium. Heart disease does not prevent psychiatrically indicated lithium treatment, but consultation with a cardiologist may be prudent. Lithium treatment should be discontinued or the dosage reduced temporarily in patients suffering from somatic illness with fever, as well as in patients on a low salt diet, on a strict slimming regimen, or starting treatment with diuretics.

A moderate rise in the frequency of congenital malformations has been seen among children born of women given lithium during the pregnancy. As a general rule, it must be considered advisable that fertile women use contraceptive measures during lithium treatment, that lithium is stopped by women who plan to become pregnant, and that it is discontinued as soon as an unplanned pregnancy has been discovered. The individual patient's situation must be considered, however, and sometimes the doctor and prospective parents may decide to continue lithium treatment in spite of pregnancy when previous discontinuations have led to rapid development of severe manic or depressive relapses.

Alternatives to lithium

Not all manic-depressive patients respond to lithium, and some do not tolerate it. A search for prophylactic alternatives is therefore indicated.

It is now well established that continuation treatment with antidepressant drugs prevents depressive recurrences significantly better than placebo. A prophylactic effect against manic relapses has, however, not been demonstrated, and there is evidence from systematic studies, confirming clinical impressions,

that long-term treatment with antidepressants may precipitate manias. Some studies have shown lithium to prevent depressive recurrences more effectively than antidepressants; other studies have shown the opposite. In either case, patients with a unipolar disease course have an option; if one kind of treatment does not work or is not tolerated, then the other can be tried with a fair chance of success.

Until recently, bipolar patients have been in a different position. Long-term administration of neuroleptics may prevent or ameliorate manic recurrences, but does not prevent depressions. Promising results have, however, been obtained with the antiepileptic drugs carbamazepine and valproic acid. The studies have mostly been carried out on patients who were refractory to lithium. It has not yet been clarified whether these drugs are most effective alone or in combination with lithium, nor whether there are circumstances when one of them should be the first choice prophylactic agent.

Many other drugs or procedures have been suggested as prophylactic alternatives to lithium. They include repeated electroconvulsions, sleep deprivation, benzodiazepines, L-tryptophan, L-hydroxytryptophan, rubidium, beta-blockers, and L-thyroxine. Prophylactic action better than that of placebo has not been unequivocally demonstrated for any of them.

Patient-physician co-operation

If long-term maintenance treatment is to give satisfactory results, it must be based on close and confident co-operation between doctor, patient, and family. This is important with manic-depressive illness, a disease that profoundly affects personality and interpersonal relations, and it is essential with lithium, often perceived as a drug with effects directly on the self. Many problems arise along the treatment course which may tempt the patients to interrupt therapy or to be noncompliant.

The very efficacy of lithium prophylaxis may be a reason why patients tend to discontinue treatment. When there have been no relapses for a long time, the patients think that treatment is no longer necessary and stop it, often with dire results. Doctors should specifically warn against the risk of relapse.

Patients with a bipolar disease course may, during effective lithium prophylaxis, miss the productivity, surplus energy, and social ease of the light manias, and for this reason stop the treatment. It is not always the elation that is missed; the family may blame the patient for lack of depth when he or she no longer has depressive episodes of sadness and humility.

Patients may discontinue lithium because it does not work, or does not work as well as they had expected. They may be disappointed because the treatment did not solve all personal and marital problems. There may be factors in the patient's life which tend to maintain the disease pattern and the patient role. The patient may not have taken the tablets regularly, or may have been treated for an insufficient time. Patient and doctor must together try to analyse reasons for incomplete response and discontent.

There are patients who have difficulty accepting that they must be in long-term drug treatment. Sometimes pronounced anti-drug attitudes prevail among family and friends, who urge the patient not to start

treatment or to discontinue it against medical advice. Psychiatrists should spend ample time correcting such misconceptions through the provision of full and sober information about the illness and the treatment.

Careful information and instruction are cornerstones in successful long-term lithium treatment. The patients should be given information in written form as well as verbally, and the doctors must be prepared to discuss problems as they arise. Books written specifically for patients and relatives are available in several languages; they may serve as a basis for discussions between doctor, patient, and family.

Lecture

Some Relationships Between Psychiatry and the Social Sciences*

D. MECHANIC

Beyond assuring biological survival, every society must have structures that nurture the young, prepare them for social roles and responsibilities, and that successfully integrate them with a reasonable level of motivation into ongoing patterns of activity. Societies must also have institutions that reinforce a sense of personal commitment to everyday affairs: the lack of a stake in social processes contributes to personal demoralisation and deviant behaviour. Deviance may also occur because of biological vulnerability or handicap, because socialisation fails, because demands exceed capacities, or as a result of sub-group identification being in conflict with dominant values. Psychiatric disorders are a sub-set of deviant behaviour.

The incidence and course of most psychiatric disorders are a product of complex interactions between biological propensities and social, cultural, economic, and demographic forces. The human organism is extraordinarily adaptable to variations in geography, climate, culture, and social organisation; most people, whatever the environment, adapt without mental illness. Some populations undergo horrendous conditions of deprivation and adversity, at times resulting in extraordinary rates of impoverishment, hunger, physical abuse, and mortality; the remarkable fact is the resilience of the human organism, and its ability to persevere despite massive assault. Persistently high levels of stress can push most individuals to their psychological breaking points, but even severe limitations of physical security and assaults on psychological well-being have differential effects on those subjected to these conditions, depending on biological vulnerabilities, coping capacities, supportive relationships, and

the meanings which individuals attribute to their situations.

The social sciences are broad in their concerns, examining social structures and change, as well as developmental processes over the life span. Their concern with the determinants of adaptation and how it is shaped by social institutions such as the family, economic arrangements, and social relationships are intimately linked to basic concerns of psychiatry. How societies structure the learning and decision-making necessary for successful adjustment, and how they programme everyday life in the family, at school, at work, and in many other interactional contexts, influences the psychological skills, predispositions, and personal inclinations that are linked to social functioning, psychological well-being, physical health, and mortality. Societies generate different rates and patterns of pathology, depending on demographic, economic, and psychosocial influences that interact with the biological potentials and limitations of human organisms.

I propose to discuss some general perspectives that encompass much effort in the social sciences which is relevant to psychiatry. These include: the concept of the life course; the influence of social stratification; stress and coping processes; social selection; and illness behaviour.

Social scientists in a variety of disciplines have adopted a life-course perspective which examines individuals and the important units of which they are part (such as the family) within a longitudinal frame of reference (Elder, 1985). The ageing of both individuals and these social units has a unique history, and this reminds us of the extraordinary differences in formative influences experienced by varying generations (Ryder, 1965). This perspective also takes account of the abundant evidence that an individual's life-course, and experience at any point, is dependent on earlier influences and choices that affect the range of options at subsequent points. Choices about schooling, job, marriage, childbear-

*Presented at the World Psychiatric Association 25th Anniversary Symposium, Copenhagen, August 1986. This paper will also be published in the Symposium plenary papers.

ing, and their timing, establish the conditions for future transitions (Brown, 1986). Thus, while the life-course perspective teaches us that there are many ways to age, it also illustrates the inter-connection of events and how life chances are narrowed by particular experiences and choices.

The study of birth cohort differences has been a major analytical advance in social science: each cohort has varying opportunities, depending on demographic factors and the unique historical conditions it experiences, as it progresses through the life cycle. Even the size of a particular birth cohort (Easterlin, 1980), relative to others, in interaction with economic conditions and values, can either provide opportunities or set limits on life chances. If jobs are few, a large cohort of entrants to the job market relative to retirees can affect the fulfilment of aspirations and economic and occupational success. Similarly, the size of cohorts, in combination with cultural conventions for men to marry women younger than themselves, may restrict marital opportunities; when this is combined with existing patterns of differential mortality by sex, it becomes inevitable that many women in Western societies will have long periods as widows.

In psychiatry, as in medicine more generally, age is an important marker because of the different times of onset of varying illnesses, and the age-structure therefore in part determines the burden of illness. With improvements in longevity and the reduction of fertility, many of the world's populations are significantly ageing. In Western industrial societies, these demographic transformations, resulting in proportionate increases of elderly populations and increasingly of the oldest sub-groups, substantially affect the prevalence of Alzheimer's disease, other dementias, and chronic disability (Gruenberg, 1977). These patterns of frailty put extraordinary burdens on families whose capacities for caring have already been weakened by changing household structure, divorce, and women's increased participation in the labour force. Mental confusion, and the behaviours associated with it, are major precipitants of institutional admission, thus putting large economic strain on health and social welfare budgets in many nations.

The size of the large cohorts born after World War II in the United States and other Western countries has provoked much analysis of their impact on future eligibility for social welfare benefits. From a psychiatric perspective, these large birth cohorts have now reached ages of greater risk for major psychiatric disorders. If risk factors remain the same or are even somewhat reduced, the larger populations at risk still result in a greater burden of mental illness. Thus,

these differences in size of birth cohorts become extraordinarily important for psychiatric planning.

There are further implications from a life-course perspective. The behavioural profiles of varying cohorts of psychiatric patients reflect the social ideologies and treatment patterns that prevailed during their formative development. Psychiatrists in Western countries increasingly complain of the new young chronic patients who often are uncooperative, disruptive, and intractable as patients. Many of these younger patients grew up in a cultural context characterised by deinstitutionalisation, a strong civil liberties orientation, and ideologies denying the validity of mental illness or psychiatric knowledge. Such patients have different illness behaviour from earlier cohorts, and have had varying experiences with mental health services. Their greater intractability and possible alternative approaches to their care are best understood in the context of attitudes and values that are shaped culturally during periods of formative development.

The composition of the population of psychiatric patients at any point in time depends on the experiences of different cohorts, as well as on the organisation of treatment and social welfare. The growth of the hospitalised mentally ill in Western countries in the first half of this century was due in part to increasing longevity and the growing number of elderly patients with dementias, to the accumulation of patients in hospitals with tertiary syphilis, and the lack of custodial alternatives (Grob, 1983). In the United States, deinstitutionalisation did not gain momentum until 1966—more than ten years after the widespread introduction of neuroleptic drugs: the accelerated trend to community care followed important social welfare legislation that paid for alternative institutional care and community subsistence (Gronfein, 1985). As a consequence, elderly patients with dementias were relocated to nursing homes, while many younger patients returned to the community, subsisting on their disability benefits.

The life-course perspective has provided a deeper understanding of the continuity of experience, and of the differences between chronological age and social and biological age. Even birth cohorts distanced by as little as five years can have different biological outcomes at a given age (Svanborg, 1986). By identifying risk factors early, and by changing habits and social practices, we have the ability to modify outcomes throughout the life-span. Most important from the conceptual point of view, however, is that we have learned to differentiate age from disease, despite their statistical association, and increasingly find that incapacities typically attributed to ageing are the consequence of disease and not age. We

are also learning better how to maintain the capacities of the elderly, including memory and motor capacities, by teaching coping skills and by training members of their supportive networks to help reinforce behaviours which are consistent with enhanced functioning.

Our achievements, thus far, have been more in sharpening our questions, improving our research instruments, and developing more powerful analytical strategies, than in identifying successfully the complex pathways between biology, society and culture, and states of mind. We now deal more typically in probability and risk, and less in causal certainty, but the precise mechanisms that operate among these important realms of experience remain to be elucidated. In recent years, there has been much work relating social and psychological events to physical end-points such as cardiac functioning and immune response; this suggests that we are getting closer to truly developing a biopsychosocial model (Mechanic, 1986a).

The current research literatures on such issues as stressful life events, appraisal and coping processes, social support, and the sense of personal efficacy and control represent new ways of confronting long-standing issues. The study of how individuals relate to one another, to social groups, and to systems of symbolic meaning, and the implications of these relationships for pathology has been an important focus of study since Durkheim's classic work on suicide in 1897 (Durkheim, 1951). The study of social networks and social supports—a vigorous area of research activity—continues to examine issues examined by Durkheim (Cohen & Syme, 1985). Even in the most extreme environments, persons often increase their adaptability by developing social connections that provide acceptable meanings, information and assistance, and support and protection. These informal organisations, at times taking elaborate forms, have been described in concentration camps, prisons, custodial mental hospitals, refugee camps, ghettos, and areas experiencing disaster (Mechanic, 1974). Social networks and processes of social support have been studied in almost every conceivable situation, and the literature provides much evidence that deficiencies in networks are related to a lack of social well-being, psychological distress, the occurrence of illness, and even rates of mortality (Cohen & Syme, 1985). But the evidence also suggests that social connections are part of a larger, more complicated constellation of influences, and increasing attention focuses on processes of stress and coping.

Each of the relevant component areas of the stress-coping paradigm (the measurement of stress, the

description of social networks, and depiction of the coping process) is characterised by vigorous debates about assumptions, conceptualisation, and methodology, but these debates have significantly sharpened thinking. In the measurement of stress, divergent views abound on the emphasis to be given respectively to positive and negative life events, subjective and objective measures, and major life events as compared with daily irritations. There also has been controversy as to the methodology of measuring events (whether by respondent report or independent evaluations), the significance of precisely timing the event, and the need to distinguish carefully between events totally outside the individual's control, as compared with those to which the person could have contributed such as divorce, loss of job, or economic difficulties (Brown & Harris, 1978; Dohrenwend & Dohrenwend, 1981; Lazarus & Folkman, 1984). The value of focussing on independent events is clear, but relatively few stressors are completely independent of a person's past history or behaviour.

The concept of social support has been subjected to similar types of debates. While the evidence linking measures of social support to health outcomes has been substantial, neither the measurement of the concept nor the results have been fully consistent. The concept may refer to the extent and structure of social networks, the availability of intimate others, social contacts, voluntary community participation, and similar phenomena. Theories underlying alternative approaches to measurement have not always been clear, and the specific causal mechanisms intervening between support and outcomes are not well developed, although specification of alternative statistical models has advanced (Wheaton, 1985). Studies of support have been relatively one-sided, with little attention having been paid to the constraints, responsibilities, and stresses often associated with kinship ties and other close interpersonal relations.

Decisions about measurement often involve assumptions that close the opportunities to examine particular theoretical ideas. Life event scales that failed to differentiate clearly between positive and negative life changes made it impossible in many studies to test the assumption that life changes, independent of positive or negative features, contributed to morbidity. Existing evidence suggests that loss events relate to depressive illness, but that a wider range of events may be relevant to triggering schizophrenic episodes. Measurement approaches must allow testing of the underlying assumptions that motivate investigation in the first place. Similarly, the counting or scoring of life change events, in examining direct relationships between life change

and health outcomes, ignores much developmental research which suggests that growth and competence are attained through mastering challenging life events. Within this context, stress describes a relationship between a situation and an individual's resources to deal with it, and not a specific event (Lazarus & Folkman, 1984; Mechanic, 1978). The most typical measurement models are not always well constructed to capture the richness of our ideas.

The examination of people's sense of personal control, and the exercise of 'mastery', is a large and promising research area; this has immediate practical implications because it is possible to intervene in many social contexts to enhance people's control over their immediate environments (Rodin, 1986). It is also consistent with developments in clinical psychology and cognitive therapy which relate to helplessness and depression. In some contexts studied, such as nursing homes, small changes in personal control have an impressive effect on psychological response, health, and even mortality (Rodin & Langer, 1977), but questions about this remain unanswered. It is not apparent to what degree these effects operate within the normal range of human control, compared with situations of deprivation. Nor is it evident how enhanced control interacts with personality, attribution styles, cultural values, age, and other variables. The area remains an important one for continuing research and theoretical development.

The study of social stratification and psychiatric disorder has had a central place in sociology and psychiatric epidemiology for several decades, and encompasses a range of theoretical perspectives and orientations. These vary from Marxian views on stratification and alienation to more pragmatic concepts that identify strata by status, income, ethnicity, and gender, which are presumed to differ in relative power and resources (Dohrenwend & Dohrenwend, 1969). Stratification is used as a basis to study the differential incidence and prevalence of disorder, pathways into treatment, types of treatment received, retention in treatment and referral, and outcomes (Mechanic, 1978).

Lower social class continues as one of the most influential predictors of the prevalence of a wide variety of psychiatric disorders, including psychotic illness, substance abuse, anti-social behaviour, and high levels of psychological distress. Social class further influences such factors as access to care, pathways into treatment, types of intervention, and retention in treatment. Class, typically measured by such indicators as income, education, and occupational status, encompasses wide variation in living conditions, power relationships, social re-

sources, child-rearing practices, attitudes and values, social stresses, and other important life processes; these relationships with social class may vary by culture and nationality, as well as over time. In community studies, measures of psychological distress have been found to be inversely and independently associated with education, income, and occupational status. The relative influences of these predictors vary by sex and labour force participation, indicating complex interactions (Kessler, 1982). In short, stratification differences reflect a rich microcosm, in which the interplay between personal vulnerabilities, social adversities, psychological resources, social supports, attitudes and values, and coping processes are played out.

In the study of gender differences, most attention has been focused on the higher risks among women for depression and psychophysiological distress, with relatively less given to the excess prevalence of antisocial behaviour, personality disorder, and substance abuse among men. It is clear that gender differences depend substantially on the disorder under consideration, and efforts to identify predictors of psychiatric disorder in the aggregate open up issues for which we have no conceptual solution. Some argue that the acting-out behaviours which are characteristic of men counterbalance the female excess in depression and related symptoms, but we have no adequate specification of mechanisms to explain the processes through which comparable tensions may lead to alternative patterns of expression of distress. Current interest in vocabularies of distress and processes of somatisation across cultures provide a better grasp of how misery is managed within the limits of cultural constraints (Kleinman, 1986); but given our limited knowledge of mechanisms, research tends to focus on gender differences as they affect specific disorders or types of expression.

All human societies undergo continuing processes of sorting and resorting of their populations, influenced by biological differences, social norms, and individual inclinations and preferences. Some important sub-areas concerned with such selection include the study of assortative mating, geographical migration, and educational and occupational achievement. The study of selection gives attention to the characteristics of individuals and groups that make them different, and to the way they interact with others, exchanging information about their social characteristics, skills and limitations, and personal qualities. Efforts are also made to understand the underlying opportunity structures that may provide more or less options, and that facilitate or limit certain types of choices and outcomes.

Many scientists find social selection an irritation; because it is so influential, no hypothesis is credible unless selection is excluded as a prior explanation. Thus, in examining the effects of organisational environments, therapeutic interventions, educational efforts, etc. selection is the first hypothesis that must be investigated. These effects are widely believed to be so persistent that only randomised studies can credibly deal with them. The less obvious point is that understanding selection itself contributes importantly to psychiatric planning.

Social selection, for example, continues to be a persuasive explanation for the relationship between occupation and the prevalence of schizophrenia; environmental, social, and occupational factors may interact with biological vulnerabilities, affecting its onset to some degree, but the large social class differences are most credibly explained by the disabling consequences of this condition. Similarly, there has been long-standing interest in the uneven geographical distribution of severe mental illness: most evidence points to a migratory process, whereby disabled individuals relocate into areas where they are allowed to function at marginal levels, where tolerance for deviance is more obvious, or where social and welfare support services are more readily available.

Social selection processes also play an important role in bringing patients into treatment and into particular care pathways. Repeated epidemiological studies show that significant proportions of patients with serious psychiatric illness seek no care specifically for these problems, and most psychiatric disorder is treated within the general medical sector, if at all (Shapiro *et al*, 1984; Leaf *et al*, 1985). The processes of selection into care, and into varying sources of help, depend not only on the character and severity of symptoms but also on values, attitudes and knowledge, social influences, and the financial and social accessibility of service providers (Greenley & Mechanic, 1976). It is well established that much psychological disorder is conceptualised and presented in somatic terms, and such patients commonly resist psychiatric diagnosis.

One important sub-area of selection involves the processes of identifying, conceptualising, and responding to symptoms. Such study of illness behaviour is of growing importance in understanding the expression of illness, chronic pain, and social disability. The study of illness behaviour seeks to identify the socio-cultural, psychological, and situational determinants that make people aware of symptoms, the cognitive schemata used to interpret them, and the ways in which the financing and organ-

isation of services facilitate or impede varying kinds of care-seeking (Mechanic, 1982).

A crucial premise in the study of illness behaviour is that illness, as well as illness experience, is shaped by socio-cultural and social-psychological factors, irrespective of their genetic, physiological, or other biological bases. Illness is often used to achieve a variety of social and personal objectives which have little to do with biological systems or the pathogenesis of disease. The boundaries of illness and its definitions are extraordinarily broad, and the illness process can be used to negotiate a range of cultural, social, and personal tensions. Illness behaviour is one of many alternatives for coping with personal and social tensions and conflict (Mechanic, 1986b).

Life in modern societies is characterised by extraordinarily rapid changes in technology and social structures, by almost instantaneous transmission of information across societies and cultures, and by high levels of individualism and persistent questioning of values, life styles, and institutional patterns. Many jobs are perceived as alienating, and such important institutions as the family are undergoing transformation. In American and similar societies, a larger proportion of all births are out of wedlock, having increased in the United States from 5% in 1960 to 18% in 1980. Given recent divorce rates, we can anticipate that more than two-fifths of all children will experience divorce of their parents before reaching the age of 16 (Preston, 1985). In many instances, these children are deprived of significant attention and nurturance from at least one parent, and increasing proportions of children in single-parent families are growing up in poverty. It is difficult to believe that these transformations of family life will not pose significant risks to psychological and social development and to the acquisition of self-esteem, competence, and well-being.

Social organisations embody a wide variety of opportunities and demands that potentially challenge cognitive and behavioural capacities. They may be the source of overwhelming stress and immobilisation, or else stimulate a high level of psychological flexibility and personal competence (Kohn, 1977). The demands implicit in social roles shape psychological and cognitive orientations, complexity of thought processes, and coping abilities; thus, the social structures that emerge have extraordinary mental health implications. The challenge to the social and behavioural sciences is to describe these changing structures and their effects on human potential and individual disorder, and to elucidate the dynamics that link these macro processes with specific important health outcomes.

Aspects of the Epidemiology of Schizophrenia*

E. HARE

Reasons are given why the hospital diagnosis of schizophrenia may be accurate enough for the proper study of certain aspects of its epidemiology. Studies in the seasonality of admissions and of births in schizophrenic patients have produced consistent results in different countries and at different times. The results are summarized, and causal hypotheses based on them are discussed. The idea that schizophrenia is a relatively recent disease is compatible with these hypotheses.

Is there an epidemiology of schizophrenia?

Given the uncertainty of diagnosis, it is an open question whether there can be a useful epidemiology of schizophrenia—conflicting opinions have recently been expressed in two leading American journals (Freedman, 1984; Shepherd, 1984). The diagnostic problem is most apparent in attempts to determine the incidence rate in a general population. Because it is a comparatively rare condition, a large population is needed to give sufficient cases to establish a firm rate. In practice this means that not every individual at risk can be personally examined by a psychiatrist; this gives rise to questions of how far the use of lay interviewers and structured questionnaires are appropriate (Helzer, *et al*, 1985).

However, there are other uses of epidemiology, for which the problems of method are of a different, less formidable kind. This paper discusses evidence which suggests (a) that worthwhile epidemiological studies of schizophrenia can be based on hospital data, and (b) that the findings of such studies lead to causal hypotheses which have considerable explanatory power and point to further lines of research. It might be argued that such studies are not properly 'epidemiological', but I have presumed the epidemiological method to be the search for associations between rates of illness and levels of environmental factors in different populations.

The *advantage* of hospital data is that in every case the diagnosis has been determined from clinical interview of the patient by a psychiatrist. A series of cases can be restricted either to the first admission or to the most recent admission of persons born within a par-

ticular geographical area and resident there at the time of admission, so that a suitable population base is available. From a large geographical area (i.e. a nation or state) large numbers of cases of schizophrenia will be available for statistical analysis, and there will also be large numbers of cases in other broad diagnostic groups drawn from the same population. It has been argued (Ødegaard, 1952) that almost all schizophrenic patients will be hospitalized at some stage. Even where that is not so, a hospital series of cases will represent the more severe instances of the disorder, and thus the probability of 'correct' diagnosis will be greater. This will be true even when the chances of hospitalization vary in different areas and at different times, and when the proportion of cases diagnosed as schizophrenia on first rather than on subsequent admissions is variable.

Of the *disadvantages* of hospital data, the most obvious is that an unknown number of cases in the population will not be hospitalized; however, for the studies considered in this paper, complete case finding is not an essential requirement. Another disadvantage might be that the larger the geographical area, the greater will be the number of psychiatrists concerned with diagnosis and so the greater the probability they will use differing criteria. It seems likely, however, that in a relatively small state or nation (e.g. the UK or the Scandinavian countries), diagnostic criteria will be similar throughout, and there is evidence to support this (Copeland *et al*, 1971). For long-term studies there is the further problem that diagnostic criteria may undergo secular changes.

If, in sets of hospital cases, the associations found between rates of illness and levels of certain environmental factors are similar in different countries and at different periods of time, then this will tend to confirm the value of the method.

*Based on a paper given at the Autumn Meeting of the Royal College of Psychiatrists, 15 November 1985

Consistency of results

There is no such thing as complete diagnostic accuracy. What is needed for epidemiological analysis is a degree of accuracy sufficient to yield consistent results. A straightforward objective test may be useful here. For example, consider the differential diagnosis of schizophrenia from neurosis: the test is that cases diagnosed as schizophrenia should be distinguishable (statistically) from cases diagnosed as neurosis by a criterion which has not been involved in the diagnostic process. It isn't always easy to find such a criterion: for example, schizophrenia and neurosis differ considerably in their age-sex distribution, but it might well be claimed that a psychiatrist takes some account of these factors in reaching his diagnosis. However, no-one would claim that the month of a patient's admission to hospital, or the month of his birth, or the age of his parents at the time of his birth, are likely to have been concerned in the diagnostic process. On each of these criteria there is very strong evidence that cases diagnosed as schizophrenia show significant differences in distribution from those diagnosed as neurosis. Thus schizophrenia passes this test. Moreover, there has been considerable consistency in these findings when they have been replicated at different times and in different countries. The summer peak of admissions to mental hospitals was noted in France 150 years ago (Esquirol, 1838), and has been repeatedly confirmed for schizophrenia. An excess of winter births among mental hospital patients was first reported from Switzerland on patients admitted between the years 1870 and 1910 (Tramer, 1929), and the great majority of subsequent studies have confirmed this for schizophrenia, not only in different countries but in parts of the world where diagnostic criteria are known to have differed somewhat. Moreover, in both these instances the seasonal excess over the yearly average has generally been of the same degree: 8–10% for summer admissions, 5–8% for winter births.

The search for diagnostic precision

There is another reason why we should not shy away from an epidemiology of schizophrenia. Attempts are continually being made to increase the precision of clinical diagnosis – formerly by classification into subtypes, and more recently by laying down specific criteria. Yet it should be borne in mind that the nature of schizophrenia may be such that these attempts can never be more than partially successful. If we consider the hypothesis – a not unreasonable one at present – that schizophrenia is due to a diffuse damage to certain cerebral cells or synapses, and that

the distribution and severity of such damage may depend on many factors, such as constitution, time, or simply chance, then we should not expect to find any clear-cut syndrome. Thus the quest for precision in the clinical diagnosis of schizophrenia may be futile.

We should note too that although the diagnosis of schizophrenia remains somewhat unsatisfactory, the diagnosis of depression is very satisfactory. Most clinicians would agree that unipolar depression shows every gradation from an obvious psychosis to an ordinary bout of low spirits. In such circumstances, the decision of where to draw the line between an illness and a normal variant can only be an arbitrary one. The same would seem to apply to states of anxiety. Mania, on the other hand, can be diagnosed with more confidence, and the fact that cases initially diagnosed as mania may later come to be called schizophrenia – and vice versa – does not matter if these are being considered under the general group of functional psychoses.

Two historical examples

There are historical reasons for thinking that diagnosis need not be precise in order to yield useful ideas about possible environmental causes. For example, although colic is a well-defined symptom, its diagnosis – the nature of the syndrome of which it forms a part – would have been far from precise in England in the eighteenth century. Yet, by straightforward epidemiological methods (based largely on hospital cases), George Baker (1767) was able to show that, in those parts of England where cider was made and where severe colic particularly occurred, there was a close association between the incidence of colic and the presence of lead metal in the cider presses. He then went on to show, by chemical tests, that lead was in fact present in the cider from such presses, and that in places where the cider was free of lead there were few or no cases of the 'Devonshire' colic. He also remarked that, in outbreaks of colic on the continent some decades earlier, the supposition that these were caused by adulteration of the wine with salts of lead (used to diminish the risk of acid fermentation) was at first doubted on the grounds that the diagnosis of colic was very imperfect.

During the nineteenth century the diagnosis of general paralysis was, as Kraepelin (1913) noted, often in doubt – indeed, the apparent increase in its incidence during the last decades of the century was put down to the use of wider criteria for its diagnosis. Yet, as we can see in retrospect, useful epidemiological studies were made. Chapman (1879), by a simple analysis of asylum cases, showed that the ratio of the

rates for single to married patients was about three to one for all cases, but one to one for cases of general paralysis. He concluded that general paralysis was not a constitutional disorder (as most cases of insanity seemed to be), but was probably caused by factors acting after birth. Earlier than this, Esmark & Jessen (1857) found that patients with general paralysis gave a previous history of syphilis more often than other patients. This pointer was not taken seriously at the time, perhaps because it was then outside medical experience for 5–20 years to elapse between infection and the onset of mental sequelae. By the beginning of the twentieth century, however, the evidence of an association between general paralysis and a history of syphilis was strong enough to convince the statistically-minded – including Kraepelin – that general paralysis must be a syphilitic disease (and this was some years before Wassermann's test of the cerebrospinal fluid was discovered). The epidemiological evidence and the conclusion drawn from it was a stimulus to further laboratory research.

Seasonality studies

If we accept that there can be a useful hospital-based epidemiology of the functional psychoses, and in particular of schizophrenia, then the next step is to consider some of the findings and their possible implications.

Among the best-established findings are those of *seasonality*: seasonal variations in incidence which differ from those shown by other mental disorders or by the general population. This phenomenon of seasonality is a good reason for thinking the functional psychoses to be real conditions, and not merely social labels as some writers have maintained. Because seasonality is more simply explained in environmental terms than in genetic ones, it provides an argument for there being an environmental factor in the cause of the psychoses.

Seasonality of suicide

Affective psychosis is implicated in a high proportion of suicides; in many countries the suicide rate has been shown to vary with season, with a peak rate in the spring. The spring peak of suicides was noticed in London in the seventeenth century, and has been widely confirmed in many countries and over long periods of time. In England in recent years suicide has been the only common condition with a highest death rate in the second quarter of the year. Few people would question the reality of this phenomenon, but it is hard to account for. Durkheim (1897) offered a

social explanation – that the increasing life and light in spring-time made those who were already miserable feel increasingly cut off from their fellows – but this is a type of explanation hard to disprove. It seems more reasonable perhaps – particularly in view of the evidence (mentioned below) of seasonality in the onset of the functional psychoses – that seasonality of suicide is secondary to seasonality in the incidence of affective psychosis, as Morselli (1881) had earlier proposed.

Seasonality of onset

The date of onset of a functional psychosis is often hard to determine, but the date of a patient's admission to hospital may reasonably be taken as an index of onset. The seasonal variations in admission rate to psychiatric hospitals, with the maximum in early summer, is a well-known phenomenon (Abe, 1963) but one to which little attention has been paid. Pinel mentioned it in his *Traité* of 1801 and Esquirol (1838) demonstrated it statistically at the Sal Pêtrière Hospital in Paris for the years 1806–14 (Fig. 1): In

FIG 1 Monthly admission rates to the Sal Pêtrière Hospital, Paris, 1806–1814. There were 2499 admissions. The rates given are the average daily rate for the month expressed as a percentage of the average daily rate for the year (Data from Esquirol, 1838, reproduced from Hare, 1980)

England, monthly admissions to all asylums were tabulated by the Lunacy Commissioners for the years 1895–97; they showed a summer peak for cases both of mania and of melancholia (Fig 2). Recent data for England and Wales, based on the statistics of the Mental Health Enquiry, confirm this pattern and show it to hold both for schizophrenia and for mania (Hare & Walter, 1978). The seasonal pattern is less marked for depressive illness (possibly because of the diagnostic difficulty in separating psychotic from neurotic depression), and hardly appears for neurosis or personality disorder. No one has seriously claimed to explain seasonal variations in admission

FIG. 2 Month of admission for direct admissions to asylums in England and Wales, 1895-1897. There were 26 538 admissions for mania and 15 734 for melancholia. The ratio is the mean daily number/month to the mean daily number/year, expressed as a percentage. Three-monthly running averages were used (Reproduced from Hare, 1983b).

rates for psychosis in social terms—it has occurred in too many different countries and over too long periods of time. The phenomenon would therefore seem to imply a biological factor both in the onset and the recurrences.

Seasonality of onset occurs in many medical conditions—indeed, Hippocrates thought this was the first thing to be considered in studying a disease. The most obvious examples are virus infections, e.g. influenza, poliomyelitis, and rubella, and it is worthy of note that the seasonality of onset in insulin-dependent diabetes has been taken as evidence of a viral factor in the aetiology (Gleason *et al*, 1982). However, there are many non-infectious examples, such as pellagra, accidents in the home, and lead poisoning (the Devonshire colic had a marked seasonal variation, with a peak incidence in late autumn soon after the apple harvest; however, it did not occur *only* in the autumn, and this fact was taken by Baker (1767) to imply that the colic was not merely due to the sourness of the apples but indicated a toxic substance in the cider whose effective concentration gradually diminished with time). Where no cause is apparent, seasonality of onset cannot be taken to imply any particular kind of causal agent, but it does strongly suggest an environmental agent of some kind.

Seasonality of birth

A seasonality of birth has been widely reported for schizophrenic patients (Hare, 1983b; Pulver *et al*, 1983; Watson *et al*, 1984). Moreover, there have been

very few contradictory reports, and almost all those appeared some years ago, before modern methods of data collection became widespread. The main evidence comes from country-wide or state-wide studies in Scandinavia, England and the United States, and these studies all show an over-representation of the births of schizophrenic patients during the winter or spring months (as compared with the general populations). The subject has been reviewed by Bradbury & Miller (1985). For affective disorder the reports have been conflicting, possibly because of the difficulty of distinguishing psychotic from neurotic depressions, but there has been agreement that the season-of-birth effect is not shown by patients with neurosis or personality disorder. Mania is a relatively rare condition, and adequate series of cases are not easy to collect, but data from the Mental Health Survey in England—based on 3500 first admissions during 1970-79—show the seasonal distribution of births in mania to be very similar to that of schizophrenia (Fig. 3).

The clearest instance of a disorder with seasonality of birth is congenital rubella, with its peak in November and December corresponding to maternal infection during the spring peak for adult rubella. Seasonal variation, with a winter peak, has also been a well-recognized phenomenon in stillbirths and neonatal deaths. It is a point of interest that the extent of these seasonal variations has diminished recently, and in several countries has now disappeared (Hare *et al*, 1981).

It may be asked whether a seasonal variation of 8-10% above the yearly average is enough to be

FIG. 3 Month of birth of 22 453 schizophrenic and 3490 manic patients born in England and Wales and first admitted to psychiatric hospitals and units there in 1970-1979. Observed numbers expressed as a percentage of the numbers expected from a 1% sample of the 1971 Census. Three-monthly running averages were used. (Reproduced from Hare, 1983b).

of much aetiological relevance, and whether the seasonality might be wholly or largely attributable to a small subgroup of cases. These questions are discussed in Appendix 1.

The season-of-birth effect in schizophrenia has been dismissed as a technical artefact. This argument has been countered (Watson *et al.*, 1982, Shur & Hare, 1983), however, and does not seem to have received support. It is hard to see how an artefact could produce this effect in schizophrenia and not in neurosis (where the age distribution of hospital admissions has been very similar). We may therefore consider other explanations. Perhaps the most straightforward is that the parents of schizophrenics have an abnormal seasonal pattern of procreation. If that were so, then their other children should show the same seasonality of birth as do their schizophrenic children. In principle, this makes for a simple test; in practice, it has proved hard to get a large enough series, and the evidence so far is conflicting. Relevant here are the findings on parental age (Hare & Moran, 1979; Kinnell, 1983). A number of studies have shown the parents of schizophrenic patients to be older than expected, and the most likely explanation is that constitutional traits in the parents make for a late age at marriage. In so far as this indicates a peculiarity in the parents, the finding of raised parental age adds some weight to the theory of the season-of-birth effect being due to abnormal seasonality of parental procreation. In addition, there is evidence that the normal seasonal variations in birth rate increase with increasing maternal age (Registrar-General, 1949; Rønnike, 1981).

The damage hypothesis

The main alternative explanation of the season-of-birth effect is of some seasonally varying damage to the foetus or new-born child. One difficulty of this hypothesis is the need to postulate that such damage can be causal for a disorder which is manifested only in adult life. There are few recognized examples of this, though late heart failure from congenital malformation of the heart may be one. The examples of general paralysis and the slow virus diseases, however, show that many years may elapse between an infection and the manifestation of disease. Woodrow (1983) reported that a significant proportion of people with congenital rubella develop insulin-dependent diabetes in late childhood, which implies the possibility that they acquired the viral factor during foetal life. Also, it has been suggested on purely epidemiological grounds that in familial Creutzfeldt-Jakob disease the infection (which

causes dementia in late life) occurs in infancy or early childhood (Masters *et al.*, 1981).

If foetal or neonatal damage is causal in the functional psychoses, we might expect to find evidence of brain damage long before the disorder becomes manifest. A number of studies support this idea. The brain abnormalities which have been described in schizophrenia are detectable in the earliest stages of the disease (Weinberger *et al.*, 1983), which suggests the damage was present before onset. Among schizophrenics with abnormal computerised tomography scans, a record of poor premorbid adjustment has been found (Weinberger *et al.*, 1980). In a study of monozygotic twins discordant for schizophrenia, ventricular enlargement was present in both twins, implying that it was not the manifest schizophrenia or its treatment which caused the enlargement (Reveley *et al.*, 1982).

The hypothesis of foetal or neonatal damage is at present, perhaps, the strongest contender to explain the season-of-birth effect in schizophrenia. What might be the cause of such damage? Complications of pregnancy or birth (McNeil & Kaij 1978), a dietary deficiency or a viral infection are the most obvious contenders. Considering the world-wide prevalence of schizophrenia, a dietary factor seems unlikely. Of the other two, a viral hypothesis has the advantage of being able to explain not only the seasonality of births in schizophrenia but also its seasonality of onset and recurrence.

Variations in incidence over time

The concepts of the disorders we now call schizophrenia and affective psychosis were elaborated by Kraepelin in 1899 under the names dementia praecox and manic-depressive psychosis. He distinguished these from among the various types of mental disorder previously grouped under the general term 'insanity'. A historical study of cases of insanity will therefore include all cases of what would now be called schizophrenia and affective psychosis (which together constitute the principal part of the functional psychoses). Certain historical studies of this kind have a special interest when seen in the light of the seasonality findings.

There is a considerable body of evidence that insanity—in the old sense—was rare in non-industrialized countries during the nineteenth century. This might only reflect the limited skill or thoroughness of the observers. However, a recent review of the evidence (Torrey, 1980) suggests it should not simply be dismissed. There is a curious parallel here with general paralysis, which was commonly reported during the nineteenth century to be

rare or absent in non-industrialized countries (Hare, 1959). The same explanations were offered in each case: either the observers failed to look closely enough, or the disorders were indeed absent and were later introduced by contact with 'civilization'. For general paralysis, the argument for its spread by contact with the West became more plausible once the infectious nature of its cause was known.

The possibility that a causal agent of the functional psychoses was introduced into non-industrialized countries during the past hundred years or so raises the question of whether these psychoses have always been present in the West (as has been commonly supposed) or whether there was a time when they were rare or absent. On some theories (e.g. Bleuler, 1972) schizophrenia must always have been with us. Two lines of study suggest that schizophrenia may be a disease of quite recent origin, however.

There appear to be few, if any, convincing descriptions of a schizophrenia-like disorder before the nineteenth century. (For an alternative view see Jeste *et al.*, 1985.) The book *Schizophrenia 1677* by Macalpine & Hunter (1956) springs to mind, but the case described there does not seem to me to justify their title. The lack of a description is the more remarkable in that during the second half of the eighteenth century (and probably deriving from the success of Linnaeus' system of classification), many books were written in England describing the varieties of mental disorder. Haslam, in the first edition of his *Observations on Insanity* (1798), gave no description which we could see as schizophrenia, although in *Observations on Madness* (1809) there are some intimations. The earliest unmistakable description that I have been able to find is that given by Haslam (1810) in *Illustrations of Madness Exhibiting a Singular Case of Insanity*. What he considered to be a 'singular case' we would now think a fairly typical case of paranoid schizophrenia.

This lack or rarity seems surprising in view of the striking features—delusions, auditory hallucinations and thought disorder in physically healthy young adults—which have been characteristic of acute schizophrenia in the twentieth century. The position here is as for a number of other conditions—syphilis, general paralysis, diphtheria, rheumatoid arthritis—whose antiquity has been disputed. In the course of the nineteenth century, however, the problem of insanity was forced increasingly on public attention and gave rise to what has been called 'the asylum era'. In England the prevalence rate of insanity increased by a factor of four to five. It was argued that the increase did not necessarily imply an increase in incidence; it might only reflect the inclusion of milder cases. It was also argued, however, that the statistics

meant what they seemed to imply—that insanity in England was 'fearfully on the increase'. The question was not resolved then, and recent historical studies (Hare, 1983a; Scull, 1979) have still not resolved it. Cooper & Sartorius (1977) considered that there had been no increase in the incidence of insanity but an increase in the number of chronic cases; Scull (1979) considered the increase to be due to increased recognition and to the inclusion of milder cases, and Hare (1983a) considered that there had been a real increase in incidence (and see a reply by Scull, 1984). If the psychosis rate did increase during the nineteenth century, that would support the view of schizophrenia being largely a recent disease, and due to some new environmental factor.

Conclusion

The principal reason for doubting that the diagnosis of schizophrenia is sufficiently accurate to allow a useful epidemiology is that incidence studies in general populations have been discrepant. The results of seasonality studies, based on hospital cases, have however been notably consistent; it is therefore reasonable to conclude that, for this aspect of epidemiological study, the hospital diagnosis of schizophrenia has been adequate.

Serious uncertainties remain. The seasonality of hospital admissions may not truly reflect the seasonality of onset, for example. The seasonality of births in schizophrenia (and perhaps also in mania) is a phenomenon with few parallels in medicine, so there is an understandable caution in accepting it as real; if it is real, an explanation in terms of parental abnormality has not been excluded. Nevertheless, the seasonality findings are in accord with the hypothesis that there are environmental factors of a physical kind in the cause of schizophrenia, and as Crow (1984) has pointed out, the range of possible factors is limited.

The idea of schizophrenia (or a common type of it) being a recent disease is still only tentative. It is of interest because it provides a scenario which can account for many aspects of the history of schizophrenia—such as its changing nature during the present century, and its 'persistence' in spite of the low fertility of sufferers—and also because a recent origin of schizophrenia would most simply be explained in terms of the same kind of environmental factors which would explain the seasonality findings.

Appendix 1

If a seasonal variation is of cyclic type (as those of schizophrenia appear to be), then a seasonal rate of 8–10% above the yearly average will be balanced by a similar rate below this average. The

maximum rate will therefore be some 20% higher than the minimum rate, a difference which might well be considered to have possible aetiological relevance for so common and serious a disorder as schizophrenia, for which nothing useful is yet known about the cause.

A seasonal variation in incidence rate may be due to a causal factor which acts in all (or most) cases but whose severity varies with the seasons, lead poisoning is an example (Stark *et al.*, 1980). Alternatively, a causal factor may act only (or chiefly) on a subgroup of cases, causing an increased seasonality among these, while the remaining cases show little or no seasonality; patent ductus arteriosus is an example (Rutstein *et al.*, 1952). As the degree of seasonality in such a subgroup (if there is one) cannot be foretold, its demonstration may be almost as difficult as the demonstration of seasonality was in the original group, in the case of schizophrenia, this required large numbers of cases and many replications before the findings came to command a degree of confidence.

Studies of seasonality in subgroups of schizophrenia have not so far shown much consistency. Dalen (1968), among 10 171 patients,

found that those who had been in hospital less than three years showed a more marked seasonality than the rest, though in both groups there was a winter peak. In a later study on a larger series of cases (which included those of the first study) this finding was not confirmed (Dalen, 1975). Pulver *et al.* (1983) found a significant birth seasonality (with a peak from January to April) in 1184 schizophrenic patients aged 17–23 hospitalized for less than six months, but no significant seasonality among 271 hospitalized for longer periods. Shensky & Shur (1982) found a significant difference in the birth seasonality of 377 patients with a family history of mental disorder (with a peak in May) and 598 with no such history (peak in October). Machon *et al.* (1983) found winter births to be more common among 125 high-risk urban born schizophrenic patients than among 48 low-risk non-urban born ones. Watson *et al.* (1984) found a significant excess of winter births in 1829 unmarried schizophrenic patients, but no significant seasonality in 1417 married ones. Nasrallah & McAlley-Whitters (1984) found a significant excess of winter births in 113 females with non-paranoid schizophrenia, but not in 135 with paranoid schizophrenia.

Childhood Hyperactivity

E. A. TAYLOR

Severe degrees of inattentive and restless behaviour in childhood are a risk factor for later psychological disorders. They have many causes, but a pattern of severe and pervasive hyperactivity with poor concentration in the absence of affective or psychotic disorders should be recognised as a hyperkinetic syndrome. The syndrome is often associated with developmental delays in abilities such as language and motor control. Powerful short-term treatments are available, but long-term ways of promoting normal personality development need more research.

Hyperactivity means an enduring style of behaving in a restless, inattentive, and disorganised fashion. These are common complaints in children, and they have many different causes. When the problems are severe, they can handicap a child's learning and relationships with family and peers, and make him or her vulnerable to further psychiatric disability.

There has been a confusing debate about the existence of a psychiatric condition of hyperactivity. It has been argued that hyperactive behaviours are non-specific features of any psychopathology (e.g. Sandberg, 1981; Shaffer, 1980). Other authorities (e.g. Aman, 1984; Wender, 1971) recognise them as signs of a specific disorder. Most diagnostic schemes recognise a distinct category. DSM-III (American Psychiatric Association, 1980) describes a condition of Attention Deficit Disorder that may be with or without hyperactivity. The former (ADHD) is defined by the presence of specified numbers of symptoms of developmentally excessive activity, attention deficit, and impulsiveness, especially at school, and affects about 3% of schoolchildren. ICD-9 (World Health Organisation, 1980) is less precise, but describes a condition of 'hyperkinetic syndrome' that is defined by short attention span and (in younger children) by 'extreme' overactivity not attributable to any other condition (Rutter *et al.*, 1975). In practice, this has led to hyperkinesia being a rare diagnosis in the UK.

Historical sketch

Severe overactivity has been recognised as a symptom of disorder in handicapped children for at least a century (Ireland, 1877). A lecture series by the pioneer of paediatrics, Frederic Still, promoted the wider idea that organic disorder of the brain was a major cause

of behavioural problems in childhood, through the induction of "defects of moral control" (Still, 1902). His description of affected children was strikingly similar to modern definitions of hyperactivity: it included "an abnormal incapacity for sustained attention", restlessness, fidgetiness, violent outbursts, destructiveness, non-compliance, choreiform movements, and minor congenital anomalies. Still's work helped to create an intellectual climate in which hyperkinesia and brain dysfunction became almost synonymous.

The next step in recognition came with the encephalitis pandemics in the wake of the First World War. Schachar (1986) studied contemporary reports, and commented that severe behavioural sequelae of encephalitis were uncommon and diverse. The cases did, however, emphasise that brain dysfunction is a possible cause of overactive and disinhibited behaviour. In this tradition, Kahn & Cohen (1934) described three cases of "organic drivenness"; their paper was influential in arguing that hyperactivity was the central behavioural abnormality, and that it resulted from disorganisation at the level of the brain stem.

The idea of hyperactivity soon became more widely applied. It was accelerated by the chance discovery of amphetamine's powerful action in reducing hyperactive and disruptive behaviour (Bradley, 1937). By 1938, Levin was able to identify more than two hundred restless children, compare them with normally active controls, and conclude that cerebral lesions caused severe restlessness (while milder degrees resulted from upbringing problems). Strauss's writings in the 1940s and 1950s broadened the idea further (Strauss & Lehtinen, 1947), to the point where hyperactivity—in the absence of a family

history of subnormality—became sufficient evidence for a diagnosis of brain damage.

Laufer *et al* (1957) described "hyperkinetic impulse disorder" in children with emotional and conduct problems, most of whom did not have any overt evidence of brain damage. They reported a low threshold for induction of muscle jerks by metrazol and stroboscopic light; amphetamine restored the threshold to normal. The study was intended as a corrective to psychoanalytical views that strongly emphasised parents' contributions to children's problems. It was followed by an explosion of biological and pharmacological research, and by a great increase in the diagnosis of hyperactivity and the prescription of stimulants by American paediatricians.

A task force produced an influential document that regarded hyperactivity as a synonym for 'minimal brain dysfunction', and included an excessively wide range of children's psychological difficulties embracing most problems presented for psychiatric help (Clements, 1966). Hyperactivity, or ADHD, has remained the commonest psychiatric diagnosis for North American children. It has generated much good research, most notably into the cognitive deficits of affected children (reviewed by Douglas, 1983) and the nature of the action of stimulant drugs (reviewed by Cantwell & Carlson, 1978, and Rapoport, 1983).

In sharp contrast, British child psychiatry and paediatrics largely avoided the efflorescence of hyperactivity. Widely quoted papers by Ounsted (1955) and Ingram (1956) described series of severely disturbed children, all of whom were drawn from the authors' patients with overt neurological illnesses. The Isle of Wight surveys (Rutter *et al*, 1970) emphasised the infrequency of hyperkinetic syndrome in a whole population of nine year-olds. The diagnosis is still made sparingly, and around half of those receiving it are intellectually retarded or show signs of neurological illness (Thorley, 1984a). This narrow concept suffers, paradoxically, from vagueness of criteria, and has led to much less research than has stemmed from ADHD.

The attitudes of European nations have generally lain between these extremes, and rates of stimulant prescription vary enormously (World Health Organisation, 1985). Several different concepts of hyperactivity have evolved in different traditions, and taxonomic research is particularly necessary.

For clarity, I shall adopt arbitrary definitions to maintain some separation between concepts. 'Overactivity' will mean simply a quantitative excess of movement, without any necessary implication of inattention or disorganisation. 'Hyperactivity', as above, will refer to an excessively high level of

inattentive and restless behaviour. 'ADHD' will refer to the DSM-III category and also to other, similar diagnoses used by North American, Australasian, and other workers; it is a relatively broad group, not only because there are few exclusion criteria, but also because impulsiveness and school misbehaviour can contribute to the diagnosis. 'Hyperkinetic syndrome' will be taken to mean the narrower style of diagnosis, often applied to severely disturbed children; criteria for a useful definition will be suggested below.

Taxonomy

Statistical studies make it clear that several symptoms of hyperactivity covary. Short attention span, distractibility, restlessness, constant fidgeting, and off-task activity are the most constant of these. They form a separate component in many independent factor-analytic studies of rating scales (e.g. Trites *et al*, 1982; Taylor & Sandberg, 1984). This 'hyperactivity factor' is distinct from one of defiantly or aggressively antisocial conduct. Nevertheless, some behaviours—such as disruptiveness, excitability, or impulsiveness—can appear as a part of either factor, and are probably non-specific.

The emergence of a factor of hyperactivity is only one step on the road to a rational classification. Most of the children referred for help because of their disruptive behaviour show both hyperactivity and antisocial conduct. Most hyperactive children are defiant or aggressive too; most antisocial children are somewhat hyperactive (Cantwell, 1980; Stewart *et al*, 1981; Taylor, 1986b). It is therefore crucial to determine whether the idea of hyperactivity has predictive and discriminative validity: does it predict anything that is different from conduct disorder? Shaffer & Greenhill (1979) demonstrated how resolutely this question had been ignored by investigators, and how little reason there was to base research or clinical practice on a widespread diagnosis such as ADHD. Researchers must therefore identify pure cases of hyperactivity that do not show conduct disorder, and pure cases of conduct disorder for comparison; otherwise, they must separately associate the two dimensions with other clinical features.

Distinction between hyperactivity and conduct disorder

Direct observations of children in playrooms or laboratories have provisionally confirmed that inattentive-restless behaviour (judged from case histories or from research interview techniques) predicts high observed levels of off-task activity, while defiance or aggression does not (Milich *et al*,

1982; Taylor *et al.*, 1986a). Furthermore, the same groups of investigators have found that hyperactivity at home or at school correlates with the presence of developmental delays (such as motor clumsiness and low IQ) rather than with psychosocial factors. Conduct disorder, by contrast, is linked closely to indices of unsatisfactory family life, such as discord between family members, low levels of expressed warmth, and ineffective styles of coping (Loney *et al.*, 1978; Taylor *et al.*, 1986a). A comparison of pure hyperactivity with pure conduct disorder by Stewart *et al.* (1981) also suggested that hyperactive children were symptomatically distinct; on the other hand, the two groups had equally high rates of antisocial relatives (Stewart *et al.*, 1980).

These studies were based on clinical groups; McGee *et al.* (1984) reported an epidemiologically based sample. Small numbers and missing data made conclusions uncertain, but the children with the single problem of conduct disorder had higher performance IQs than those with pervasive hyperactivity solely: socioeconomic status, perinatal history, and family relationships did not distinguish between the groups.

Existing studies of the taxonomic questions are too few to allow sharp and certain definitions. They suggest (but not conclusively) a valid separation of patterns of disorder. It is therefore worth considering the lessons from some less powerful studies, that have compared hyperactive children with other kinds of disorder, but have not included the requirement that the contrast group should be quite free of hyperactive behaviour.

Koriat *et al.* (1985) have described a notable lack of differentiation between children referred to a paediatric psychiatry service in North Carolina who received different DSM-III diagnoses. Those with ADDH alone, ADDH plus other diagnoses, and other psychiatric diagnoses not combined with ADDH, were not even distinct in terms of ratings of symptoms—let alone in demographic factors or psychological test scores. Sandberg *et al.* (1978) also found that different levels of severity of hyperactivity carried few implications for aetiology within a group of boys referred to a psychiatric clinic, when 'hyperactivity' was measured by a parental questionnaire, or a teacher rating scale, or by a single period of direct observation at a clinic. Each of these measures was imperfect; when they were combined, a small group of children with pervasive hyperactivity across all measures could be separated from the others, and proved to have an earlier onset, more signs of motor clumsiness, and poorer performance on a psychometric test. Similarly, Schachar *et al.* (1981) reanalysed the Isle of Wight survey to find that pervasively hyperactive children had poorer performance on a

psychometric test, tended to come from lower social classes, and had a worse outcome than children with other kinds of disorder.

The distinction between pervasive and situational hyperactivity may not be very sharp, and some studies find the two groups to be similar (Firestone & Martin, 1979). The general point, however, is that hyperactivity can be validly distinguished from conduct disorder, but that good measures or severe degrees need to be taken if the separation is to be found.

Status of mixed cases

If the above argument is accepted, so that hyperactivity and conduct disorder are seen as separable patterns that overlap greatly in practice, what is the status of mixed cases? If they were clearly to resemble 'pure' conduct disorder or 'pure' hyperactivity, then their position in classification would be clear.

Stewart *et al.* (1981) made just such a comparison on the basis of clinical features: children with unsocialised aggression and hyperactivity (identified mainly by parental accounts) resembled those with only unsocialised aggression more than those with only hyperactivity. On the other hand, August & Stewart (1982) presented another analysis of a closely similar series of children. When hyperactivity had to have been noted in several situations, there was little difference between the children with this problem only and those who combined it with unsocialised aggression.

McGee *et al.*'s (1984) epidemiological study seemed to show that the mixed group were particularly vulnerable. Their reading was worse than that of either pure group, and their short-term outcome was worse. Such a finding is in keeping with a dimensional approach to classification: children with both problems should be predicted to have the associations of both.

A separate class of hyperkinetic syndrome?

Hyperkinesis needs to be separated not only from conduct disorder but also from emotional disorders and specific disabilities of learning. Applications of cluster analysis to simple parent questionnaire ratings have given conflicting results about the presence of a discrete group of hyperactive children (Taylor *et al.*, 1986b). Some workers find one, some do not. Halo effects and reliance on a single rater are serious problems in this research. A cluster analytical study reported by Taylor *et al.* (1986b) was based on reliable, independent measures from several sources. The most robust feature of clustering procedures was

the emergence of a small group of pervasively hyperactive and inattentive children with few emotional symptoms. This group also showed an early onset, a high rate of delays in cognitive development, and motor clumsiness. In addition, they had a much more marked response to a stimulant drug (methylphenidate).

Definition

Current evidence favours use of a rather restricted diagnostic concept of hyperkinetic syndrome, rather than the ADHD definition. Symptoms of overactivity alone are not sufficient for the diagnosis; it should be based on:

- (a) A pattern of markedly inattentive, restless behaviour (not just antisocial, impulsive, or disruptive acts) that is excessive for the child's age and IQ, and a handicap to development
- (b) presence of this pattern in two or more situations, such as home, school, and clinic
- (c) evidence of inattention, restlessness, or social disinhibition, from direct observation or testing by the diagnostician (i.e. not solely by unconfirmed reports from a child's caretakers)
- (d) absence of childhood autism, other pervasive developmental disorders, or affective disorders (including depression, anxiety states, and mania)
- (e) onset before the age of six years and duration of at least six months.

Such a diagnosis is useful, though not very common (Taylor, 1986a). It should not be missed simply because an affected child has developed antisocial conduct as well.

Hyperactivity in special subject groups

The discussion of classification above has been based on studies of normally intelligent children in the first few years of their schooling. The behaviour problems of preschool children do not yet have a stable classification (Jablensky *et al.*, 1983). In one investigation, pervasive hyperactivity in children at a day nursery predicted psychological disorder later (Campbell *et al.*, 1977); in another, even pervasive hyperactivity was not a predictive variable among nursery children (Cohen & Minde, 1983). The behaviour matters, as will be shown later, but its classification is obscure, and clinicians should be correspondingly slow to diagnose. Overactivity is also common among intellectually retarded children, but its causes are not yet clarified. Affective disorder, autism, and atypical

pervasive developmental disorder are all important causes of overactivity in this group. I have argued elsewhere (Taylor, 1986a) that some individuals should be regarded as showing a distinct hyperkinetic syndrome, but more research is required.

Prevalence

No secure prevalence rate can be given, because of disputes about what constitutes a case. Hyperactivity is continuously distributed in the population, with smaller numbers at successively higher degrees (Taylor, 1986a). No validated cut-off yet exists, so no prevalence estimate has a scientific basis.

The numbers of schoolchildren who are in practice diagnosed vary wildly: a little over 1% in two US surveys (Lambert *et al.*, 1978; Bosco & Robin, 1980), but only 0.1% in a London borough (data from the Camberwell Register)—half of the latter being intellectually retarded. By contrast, the rates derived from questionnaire surveys of teachers' ratings are much the same in the UK as in the USA and New Zealand, and range from 5% to 20% (Taylor & Sandberg, 1984). The low diagnostic rates in the UK are likely to be due to the diagnostic practice rather than the nature of the children (Prendergast *et al.*, unpublished). Chinese populations are often said to be more docile and attentive, but a survey from Beijing, based on a combination of teacher ratings and medical diagnosis of ADHD, gave comparatively high rates (3–7% in different areas) (Shen *et al.*, 1985). Hyperactivity, in some sense, evidently exists in many cultures; it remains to be seen whether it always takes the same form.

The prevalence of ADHD in boys is higher than in girls in the ratio of about 4:1 in American clinics (Ross & Ross, 1982). The ratio was similar for the narrower hyperkinetic syndrome at a London clinic, but fell to 1.6:1 for children with mental retardation (Taylor, 1986a). Girls with the diagnosis of hyperkinetic syndrome, or with the symptom of 'gross overactivity', were more likely than affected boys to show delays in cognitive development and neurological disorders such as epilepsy (Taylor, 1986a). The reason for the greater vulnerability of boys has not yet been explained. Several theories implicate damaged brain function. The greater vulnerability of male brains may well be a part of the explanation, but has not been shown to account for the whole of the enhanced risk. Adults are often more tolerant of hyperactivity in girls than in boys, at least before school age (Battle & Lacey, 1957).

Epidemiological studies in different cultures are needed to cast light on what is central to and

universal about the conditions and what is peripheral and culturally determined.

Aetiology

In spite of much research, the causes of hyperkinesis remain uncertain. Most studies have compared children referred to clinics, because of mixed behaviour problems including hyperactivity, with controls drawn from the normal population. When positive findings appear in such a design, it is hard to know whether they are associated with hyperactivity, with behaviour problems generally, with the learning disorders that are often associated, or with the factors that lead to referral to clinics.

Brain damage

Brain disease with localising neurological signs is uncommon in children with ADDH, and is specifically excluded from most research series. The narrower hyperkinetic syndrome, by contrast, is often diagnosed in children with damaged brains. Table I summarises the findings in those investigations that have used an ICD-9 style of diagnosis and reported the range of diagnoses in various samples of children. Brain damage gives rise to a high rate of virtually all the psychiatric syndromes of childhood, rather than to any pathognomonic syndrome (Rutter *et al*, 1970). Accordingly, the best index for comparing groups is not the numbers with the diagnosis of hyperkinesis, but the rate of hyperkinesis as a percentage of all diagnoses made (Table I).

The relatively high rate in neurologically handicapped groups implies that there may be a specific vulnerability to hyperkinesis in brain-damaged chil-

dren. This conclusion is not secure, for the diagnosis could in part be determined by judgements about neurological status. Explicit and independent criteria for case definition need to be developed. If there is a specific vulnerability, we do not know whether it resides in the brain damage itself or in the generalised intellectual retardation which can result. High rates of structural brain damage were reported by Reid (1980). Jenkins & Stable (1971) matched severely hyperkinetic cases (from a case register of intellectually subnormal people) with subnormal but not hyperkinetic controls: they found higher rates of cerebral palsy and other evidence of structural lesions in the hyperkinetic patients. However, the hyperkinetic patients were also more retarded on a global measure of development. Thorley (1984a), using the case records of severely hyperkinetic children, matched psychiatric controls individually for IQ level: no significant difference in rates of brain damage then appeared.

Severe hyperkinesis may have a specific neuropsychiatric predisposition; this should be investigated further. However, there is no reason to suppose that mild hyperactivity is therefore caused by mild brain dysfunction.

Perinatal trauma to the brain

This is not usually the cause of hyperactive behaviour. Case-control studies of children showing high levels of hyperactivity have usually shown little or no increase in rates of perinatal injury, retrospectively assessed (e.g. Minde *et al*, 1968; Gillberg *et al*, 1983). Cohort studies of children of low birth weight (Neligan *et al*, 1976), or of children with complicated deliveries (Nichols & Chen, 1981), make it clear that

TABLE I
Prevalence of clinically diagnosed hyperkinetic syndrome (ICD-9) as a percentage of children with psychiatric diagnoses

Study	Type of study	Patient group		
		Neurologically normal children: %	Neurological disorders or epilepsy: %	Mental subnormality: %
Rutter <i>et al</i> (1970)	Epidemiological survey	~1	12	26 ¹
Corbett (1979)	Case register	—	—	8
Reid (1980)	Clinic outpatients	—	—	15
Thorley (1984a)	Clinical records	0.9	—	2
Gillberg <i>et al</i> (1986)	Epidemiological survey	—	—	10

1. Severely handicapped children, not attending school.

hyperactivity is not particularly common in the later lives of such children. There is a small increase—as there is for other kinds of behaviour problem—but even this increase is partly attributable to coexisting family problems. Indeed, the Isle of Kauai study (Werner & Smith, 1977) suggested that perinatal damage only increased vulnerability in children with less advantaged backgrounds.

Minimal brain dysfunction

Minimal brain dysfunction has been intensively sought, so far largely in vain. Extensive reviews have concluded that there are few unequivocally positive findings of biological abnormalities in hyperactive children (Rie & Rie, 1980; Rutter, 1983b). When abnormalities have been found, their meaning is usually unclear. 'Soft' neurological signs (i.e. clumsiness and lack of coordination) are commoner in markedly hyperactive children than in other sorts of psychological disorder (Werry *et al.*, 1972; Sandberg *et al.*, 1978; Taylor *et al.*, 1986b). However, they are not yet valid as a sign of cerebral or cerebellar pathology because of uncertainty about what causes them (Taylor, 1983a).

Neurophysiological unresponsiveness

Neurophysiological unresponsiveness to stimuli is another replicated finding. Hyperactive children, by comparison with controls, probably show normal resting levels of autonomic nervous system activity. However, peripheral autonomic responses and central averaged evoked EEG responses both suggest that a new or important stimulus produces a smaller change in hyperactive children (Taylor, 1985a). This lack of reaction may not be specific to hyperactive children: diminished physiological responsiveness also characterises children with learning disorders (e.g. Maxwell *et al.*, 1974) and unsocialised aggression (Delamater & Lahey, 1983). Since these three clinical problems often coexist, which of them (or what other associated problem) is linked to unresponsiveness? We shall only know when further research untangles the various problems.

Attention deficit

Hyperactive children fail to sustain organised attention, and score poorly on psychological tests related to attention (Douglas, 1983). However, test performance can also be upset by many different sorts of psychopathology (Shaffer, 1980), and the impairment has not yet been shown to be specifically an attention problem. Although hyperactive children

behave impulsively, psychological tests of impulsiveness suggest that they respond too slowly, not too quickly (Sergeant, 1981; Sandberg *et al.*, 1978; Firestone & Martin, 1979). Although they behave distractedly, the addition of distracting information does not particularly disrupt test performance (Douglas & Peters, 1979). The deficit is present in both short tests, such as the digit span, and long ones, such as continuous performance tests. It is even manifest in a downwards shift of IQ; indeed, when IQ is allowed for, hyperactivity shows much reduced (but still present) association with tests of concentration. There is as yet no sign of a structural deficit at any one stage of processing information—rather, there is a high-level failure to allocate resources sensibly to the task in hand and to maintain self-control in organising responses.

Animal models

Animal models of hyperactivity emphasise its heterogeneity. Prefrontal damage in monkeys, ventral tegmental lesions in rats, chemical damage to dopamine and noradrenaline synthesis, foetal exposure to lead, neonatal hypoxia, and social isolation can all produce a combination of overactivity and abnormal learning that is reversible by amphetamines (Robbins & Sahakian, 1979).

Genetic inheritance

No really persuasive study has yet been made on the effects of genetic inheritance. Full siblings of hyperactive children are more likely to be affected than are half-siblings (Safer, 1973), and hyperactive children, like antisocial children, have many relatives who themselves show sociopathy or alcoholism (Stewart *et al.*, 1980). However, family interactions could explain these findings as well as genetic inheritance. The biological parents of hyperactive children living with their natural families were more likely to have had behaviour problems than the adoptive parents of adopted children (Cantwell, 1975), but this study could not compare biological with adopted parents of the same children. The adopted-away offspring of psychiatric patients were unusually likely to be hyperkinetic (Cunningham *et al.*, 1975), but a transmission of hyperactivity itself was not demonstrated. Comparisons of dizygotic with monozygotic twins suggested that the latter were more concordant with regard to several temperamental dimensions, including overactivity (Torgersen & Kringle, 1978); twin studies of children with diagnosable conditions have not yet been reported.

Chemical agents

The most controversial aspects of the aetiology of hyperactivity have come from theories implicating exogenous toxins, such as lead and food additives.

Severe lead poisoning causes brain damage, and its sequelae include hyperactivity. Lower levels of exposure can cause hyperactivity in animals, but their significance in children is still debated. High levels within the normal range are associated with small increases in problem behaviour and with lower IQ (Needleman *et al*, 1979; Yule *et al*, 1981). It is still uncertain whether these correlations reflect the damaging effect of lead at low levels of exposure, or an association with other kinds of social adversity (Rutter, 1983a). In any event, lead exposure is not the major cause of hyperactive behaviour.

In spite of the scientific uncertainties, there is a brisk trade in testing hair for lead and other minerals and in selling supposed therapies. The enterprise should not be encouraged: commercial hair measurement is unreliable (Barrett, 1985), and the proprietary treatments are unevaluated.

Food dyes and preservatives were implicated by Feingold (1975), with the suggestion that hyperactive children showed a genetically determined intolerance. Unfortunately, most trials involving elimination of food additives have given rather disappointing results: some children's behaviour improves for a while when a diet is started, but it does not usually worsen again if additives are given in a double-blind placebo-controlled fashion (Mattes & Gittelman, 1981). Occasionally, however, some children do seem to show a genuine improvement in behaviour due to the physical effect of removing additives (Weiss *et al*, 1980). The improvement is not confined to hyperactivity, but extends to 'difficult' behaviour generally. A recent trial involving exclusion of a wide range of different foods from the diet suggested that more children can be helped by a radical exclusion of many allergens; however, the trial was based on a selected sample with a high prevalence of physical allergies (Egger *et al*, 1985). Since some parents become preoccupied with diet to the exclusion of all else, more research is quite pressing.

Psychosocial factors

The psychological environment can determine the extent to which children are attentive (Taylor, 1980). It is therefore logical to seek evidence of psychosocial adversity in the hyperactive. Affected children, ascertained in a population survey of children with minimal brain dysfunction, can be distinguished from normal controls by signs of unsatisfactory family life

(Gillberg *et al*, 1983). Children who have grown up in institutions are particularly likely to be hyperactive in their classrooms, even after they have been adopted into a family home (Tizard & Hodges, 1978; Roy, unpublished). Children known to have been unwanted (because their mothers sought a termination of pregnancy unsuccessfully) are more likely to be excitable, unsociable, and hyperactive when they go to school (Matějček *et al*, 1985).

Studies such as these are vulnerable to the same criticisms that have already been levelled at investigations of physical causes: they show correlations, not causes, and point the clinician only towards the need for comprehensive assessment.

Developmental course

Hyperactivity most commonly presents during the early years of schooling. Retrospective enquiry usually finds an onset before the age of five and often before the age of two.

Infants vary greatly in their activity levels, but the individual differences are not very stable over time. Indeed, one careful study suggested an inversion in the intensity of behaviour between the age of 3-4 days and that of 2½ years (Bell *et al*, 1971): the neonates with highest magnitude, frequency, and speed of behaviours became the two year-olds with least vigour and lowest responsiveness.

In preschool children, overactivity is a common complaint made by parents, but sometimes reflects impaired parental tolerance rather than an abnormality of development. Although (as considered above) no clear hyperkinetic syndrome has been validated for this age-group, nevertheless, the complaint of overactivity should not be ignored: it predicts later antisocial disorder quite strongly (Richman *et al*, 1982).

From the age of about three years, the normal course of development involves a reduction of general level of activity in some settings but not in others (Routh, 1980). The appropriate modulation of activity can therefore be impaired by developmental delay, whatever the cause. The resulting restlessness becomes more of a problem as schooling proceeds and successively greater demands are made on children's powers of attention and self-control.

The continuities between the early years of schooling and outcome in adolescence have been examined by many follow-up studies, mostly of children referred to clinics with ADDH, contrasted with normal controls from the community (see reviews by Weiss, 1983, and Thorley, 1984b). The investigations are limited by design weaknesses (highlighted by

Shaffer & Greenhill, 1979), but taken as a whole, they suggest that the broad group of hyperactive children do not simply grow out of it. In adolescence, they tend to remain somewhat impulsive and inattentive, and to be characterised by high rates of academic failure, antisocial behaviour, and delinquency. An epidemiological study in England also found pervasive hyperactivity to be a strong predictor of persistence of psychiatric disorder between the ages of nine and 14 (Schachar *et al.*, 1981).

There is even some evidence that severe over-activity remains a risk factor for adolescents when the controls themselves show antisocial conduct. Thorley (1984b) identified children with the hyperkinetic syndrome seen at a psychiatric hospital, followed them into adult life, and compared them with matched cases of conduct disorder from the same hospital. Their adolescent outcome was characterised by more episodes of psychiatric treatment, more epileptic fits, more accidental injuries, and more placements in special schools.

In adult life, most children with ADDH do not show diagnosable illness, but the rate of antisocial and impulsive personality disorder is high (Hechtman *et al.*, 1984). It is probably no higher than that of less hyperactive children with conduct disorder (Thorley, 1984b); however, the degree of conduct disorder in childhood and the disturbance of family relationships are better predictors of an adult antisocial adjustment than is hyperactivity itself. It seems likely that pervasive hyperactivity has its major effect on development by increasing the risk that affected individuals will develop complicating problems such as educational failure or antisocial conduct disorder. If they can be protected from such complications, then a gradual improvement in adjustment in adult life can be expected.

Treatment

Multiple factors interact to cause hyperactivity; its course is largely determined by complicating adversity. Diagnosis is therefore not enough to dictate treatment; a wide assessment and a range of interventions are needed.

Drug treatment

Amphetamines and related central nervous system stimulants are the commonest treatment for ADDH in the USA, being given to more than 1 schoolchild in 100 (Bosco & Robin, 1980; Lambert *et al.*, 1978). By contrast, they are so rarely used in the UK that the

first-line drug, methylphenidate, has recently been withdrawn for lack of demand. Dogmatic guidelines are therefore inappropriate.

Scores of double-blind trials have shown that stimulants are more effective than placebo in suppressing hyperactive behaviour for children with ADDH (Taylor, 1985b). These trials are based on relatively short periods, from a few weeks to a few months; the long-term effect is less clear. Some children who have taken amphetamines for long periods are no longer getting any benefit (Charles *et al.*, 1979). Others show worsened symptoms when their drug is removed (Sleator *et al.*, 1974). Even if symptoms are controlled in the long term, it does not follow that long-term development will be improved. Follow-ups of treated and untreated groups leave it uncertain whether drug treatment is of any use over a period of years (Weiss, 1983). Accordingly, long-term treatment should only be embarked on when there is clear evidence of short-term benefit, and good supervision (including regular periods off-drug) can be provided to monitor the continuing need for therapy.

The short-term action of drugs is not paradoxical or unique to hyperkinetic children: the effects are qualitatively similar in hyperactive children, normal children (Rapoport *et al.*, 1978), normal adults (Weiss & Laties, 1962), and conduct-disordered children (Taylor, 1983b). In all these groups, they act as stimulants, not sedatives; they reduce high-frequency and off-task behaviours, and they improve performance on a variety of psychometric tests. The mechanism probably involves catecholamine neurotransmitters (Rapoport & Zametkin, 1986). Though the action is similar in kind in different groups, it varies greatly in degree.

The best and clearest indication for stimulant medication is the uncommon nuclear hyperkinetic syndrome of pervasive and severe hyperactivity and cognitive impairment in the absence of overt emotional disorder, presenting in primary school-children of normal or only mildly retarded intelligence. There are, however, other indications too. Sometimes it is desirable to induce a rapid reduction in restless, disruptive behaviour in order to bring about a change of attitude in the child's caretakers. Sometimes medication is necessary to allow a programme of learning to operate. In these circumstances, stimulants may be given to children with lesser degrees of hyperactivity. Whatever the indication, stimulants need to be planned as an adjunct to educational or psychological help.

Careful monitoring is needed, and the reader is referred to fuller accounts of drugs and their prescription (e.g. Barkley, 1981; Taylor, 1985b).

Dietary treatments

Dietary treatments are very popular with parents, and present a dilemma because of the difficulty of recognising those few children who may be helped. The diets carry the hazards of poor nutrition and the neglect of other treatments. In present knowledge, they should only be prescribed with expert help, but it is reasonable to support parents who have themselves decided on a trial.

Psychological treatments

The techniques of behaviour modification can be applied in many different ways to the treatment of hyperactivity (Yule, 1986). Operant conditioning is of demonstrated value in the short-term reduction of off-task behaviour and increase of constructive activity in the classroom. Although it may sometimes be less potent than stimulant drugs (Gittelman *et al*, 1980), it is also more widely acceptable.

Reward-based schemes of learning can also be used to reduce gross motor activity and fidgetiness (Christensen & Sprague, 1973), but the mere lessening of activity is seldom enough to help children's adjustment. They also need to learn more positive skills of learning and social interaction.

Cognitive-behavioural therapy has promise as a tool for teaching techniques of self-control and problem-solving (Bornstein & Quevillon, 1976). Systematic evaluations have indicated that it can improve performance on laboratory tests, for instance of impulsiveness (Douglas, 1983). Its value in promoting longer-term adjustment and real-life performance is not yet established.

Considerations of developmental course emphasise the importance of helping wider aspects of a child's predicament than hyperactivity alone. Adverse and coercive styles of family interaction can

readily develop, and may indicate behavioural techniques of modifying such interactions, or the training of parents in behavioural skills, or the approaches of conjoint family therapy. Educational failure is so common and important that a liaison with schools, and a consideration of special education needs, should be part of every psychiatric assessment. Many affected children acquire a very negative view of themselves as 'weird', 'rubbish', or 'stupid'; individual sessions therefore have a counselling purpose as well as that of instilling skills. If drug treatment is to be used, it needs full and repeated discussion with child and parents, lest it lead to scapegoating or to a glib alibi for bad behaviour.

Conclusions

Research continues, but provisional conclusions can be made. Severe degrees of inattentive and restless behaviour constitute a major problem for children's development, and are different from (but overlap with) conduct disorder. They probably need more recognition by psychiatrists and teachers in the UK, but may be over-diagnosed in the USA. Delays in motor and cognitive development are often associated, and may well be aetiologically important; however, they are not yet sufficiently specifically described to justify the view that affected children have a structural deficit in the processing of information from the environment. Powerful short-term treatments are available, in the shape of stimulant drugs and behaviour modification, but their long-term effect is inadequately known. Family, school, and peer relationships are usually more important than the core problem in determining eventual adult outcome. Clinical services therefore need to develop a range of treatments for affected children.

The Prognosis of Depression in Old Age

R. C. BALDWIN and D. J. JOLLEY

The initial features and progress of depressive symptomatology over 42 to 104 months are presented for 100 elderly patients admitted with severe, non-neurotic depressive states; none had experienced a previous hypomanic episode. Sixty per cent either remained well throughout or had further episodes followed by full recovery; only 7% suffered continuous depressive symptoms. Of potential prognostic factors, only male sex and poor physical health, both at presentation and developing subsequently, were associated with poorer outcomes. The view is supported that treatment with well established methods achieves worthwhile and sustained improvement for most patients.

The recent growth of psychogeriatrics has occurred mainly in relation to the major health problems posed by the dementing illnesses of late life (Arie, 1977), but while these are common, and require substantial resources for skilled assessment, management, and research, depressive states of various kinds are even more common (Kay *et al*, 1964). They produce at least as much suffering, and can be lethal, yet are potentially responsive to available treatments to a degree not yet possible with the progressive dementias. Thus, an appropriate and effective response to depressive states is a challenge to old-age psychiatric services, in that skilled intervention might be expected to produce more dramatic results than is possible with other conditions.

Although even in the elderly, depressive symptoms are more often encountered than serious cognitive decline, recent epidemiological studies (Henderson & Kay, 1984; Post & Shulman, 1985) have demonstrated a point-prevalence of only 2–3% for primary clinical depression. An additional 11–12% of the elderly in the community have been found significantly depressed, but only to a minor degree and without biological symptoms; in about half of these 'senile dysphorics', the mood disorder appeared to have been precipitated by chronic physical illness or deterioration. However, nothing is yet known about response to treatment of this important group of elderly depressives, who only rarely come to psychiatric notice. Although the prevalence of clinical depression is probably no higher than during middle age, major depression of the aged presents problems second only to those of dementia.

The clinical features of 'melancholia' were described by Lewis (1934) and Anderson (1936), while Roth (1955) reviewed the outcome for elderly patients admitted to mental hospital in the 1950s.

Post (1962, 1972) studied two cohorts treated by him as in-patients: the first in the 1950s, when electroconvulsive treatment (ECT) and leucotomy were the only effective physical treatments available, and the second in the 1960s, when tricyclic antidepressants had been added. These reports established that while permanent recovery is unusual in this group of severely ill patients, it is much more common than continuous morbidity, and that the majority of patients experience relapses that are responsive to treatment. Rather than being a gloomy prospect, this is one which encourages services to remain available for—and if possible in touch with—their elderly depressives, and prepared to identify and treat relapses when they occur.

Murphy (1983) described a cohort referred to psychogeriatric services, which chose to admit only half these patients during the period of study. Some of her findings were alarming, notably that the death rate for men in the cohort was three times that expected, and for women twice that expected. The overall outcome was summed up as 'poor' for 48% of cases, with death or dementia supervening in a further 17%, leaving only 35% with a 'good' outcome. The prognosis for those with depressive delusions at presentation was very poor indeed: only one in ten recovered by the end of the study year. An analysis of this work concluded that for the elderly depressed, "no matter what is done, a third get better, a third stay the same, and a third get worse" (Millard, 1983).

This is a very worrying situation, which might encourage pessimism and nihilism in the face of the treatable condition of depression in old age. Since it is not a conclusion which fits with clinical experience (Godber, 1983), we have examined the characteristics and outcome of patients referred to a

psychogeriatric service that manages most of its patients without recourse to admission (Jolley *et al.*, 1982), but which chose to admit these patients because they were very ill with depression.

Method

Entry criteria were: (a) age over 65 years; (b) in-patient status; (c) Feighner's (1972) criteria for depressive illness met from scrutiny of case notes; and (d) first admission under the psychogeriatric service—previous admission elsewhere might have occurred, and two patients included had been transferred from another psychiatrist. Hence, in keeping with Post's studies, cases with recent as well as remote previous depressive episodes were accepted, but those cases free from depression since the age of 60, comparable to Murphy's (1983) patients, were identified. The reliability and breadth of material in the casenotes of in-patients was likely to be greater than for patients not admitted.

Cases were recruited from the admission register from January 1976 to April 1981; the service received 2150 referrals, of whom 25% (540) were described as depressed at initial assessment. Only 511 patients had been admitted, and in 152 (30%) of these, depressed mood was considered to be a major element in the illness. There was exclusion of 52 cases for the following reasons: age under 65 years (5); organic psychosyndrome (12); secondary depression as defined by Feighner (8); neurotic depression (5) (identified where either depression was in the setting of long-standing complaints or, in two recent cases, was associated with bereavement and the Feighner criteria could not be met for even 'probable' depression); previous history of mania (6); previous history of schizophrenia or paranoid state (4); alcohol abuse (6); personality disorder (2); case notes lost (3); and diagnosis unclear (1). The 100 subjects therefore comprised roughly one in five of those described as depressed at referral.

Phase 1: index admission. Clinical and social data were recorded on a standard form. Severity of initial depressive illness was assessed by applying the Hamilton Rating Scale for Depression (HRSD) retrospectively, using all the information recorded within the first few days of admission; the clinical description of each HRSD variable by Hedlund & Vieweg (1979) was relevant here. Physical health was scored for eight body systems, according to whether there was no problem, an inactive problem (e.g. an old myocardial infarct), or an active problem (e.g. effort angina). Those discharged were classified as 'well' (free from affective symptoms), 'improved' (incomplete symptomatic recovery), or showing 'little or no change', in a manner analogous to Post (1962).

Phase 2: follow-up at one year. Clinical status one year from admission was assessed from the case notes for all but one patient, who had moved out of the area after discharge and was untraceable. Outcome was classified after Murphy (1983): (a) 'well': those recovered at one year who were

either asymptomatic or had minor symptoms insufficient to meet the Feighner criteria for depressive illness; (b) 'relapsed': those who after recovery from the index illness experienced a return of symptoms which fulfilled the Feighner criteria; (c) 'continuously ill': those who retained their depressive symptoms throughout the year, with little variation.

Phase 3: follow-up to 1984. By the autumn of 1984, 31 patients remained within the psychogeriatric service. A further 25 were dead but had been followed-up by the service from the index admission until death. Finally, 44 were no longer within the service, although 34 were known still to be alive. Re-assessment was carried out by means of personal interview in 54 cases; of the remaining 46, 35 were dead, eight were not interviewed on general practitioner's advice, or had moved too far away, and three were lost from follow-up. The personal interviews were carried out by one of us using a structured questionnaire. For all but four of the remainder, information on physical and mental status was obtained from general practitioners (GPs), social workers, officers in charge of residential homes, and others. The outcome of psychiatric and physical health was thus known for 96 of the original 100 cases from the time of admission to either death or close of study. This gave a follow-up period of 104 months for patients admitted early in 1976 and 42 months for those admitted in early 1981; the four about whom information was not complete had nevertheless been followed-up by the service for an average of 21 months.

Patients were assigned to an outcome category in terms of depressive symptoms, after Post (1972): Group 1: lasting recovery until death or close of the study; Group 2: further relapses, but with complete recovery between episodes; Group 3: some degree of residual depressive symptomatology, often with further circumscribed relapses ('depressive invalidism'); Group 4: ill with depression until death or close of the study.

In addition, the services received by these patients (inpatient, day hospital, outpatient care) and the treatments they received, from the date of first admission to exist from the study, were recorded.

Results

Characteristics of patients at entry to the study

Age, sex, and social circumstances. Women ($n=79$) outnumbered men ($n=21$) by almost 4 to 1. The age-range was 65–88 years (mean = 74.0; s.d. = 4.93), with only two patients over 85; 22% were still married, 24% were single (of whom three out of four were spinsters), 50% were widowed, and 4% were separated or divorced. Ninety-two per cent were members of a private household and 49% lived alone.

This cohort was therefore older than those described by Post, and similar to that described by Murphy; compared with Post's 1962 cohort, it included more women who were either widowed or single.

Previous psychiatric history. Seventy-nine per cent fitted Murphy's (1983) criterion for a new case, i.e. having had no previous depression since the age of 60, although 46% of the whole group had a history of depression at some time previously, and 35% had been admitted to a psychiatric hospital.

Precipitating events. Information from the case notes was judged to be adequate for 91 patients; of these, 79% had experienced a major adverse life event in the year preceding admission. The type of events were: bereavement (30%); exit of relative or close friend (13%); major health change (13%); change of home (11%); retirement (4%); and other events (8%).

Psychiatric status. All were suffering from primary depressive states as defined by Feighner, and in all but 18, the onset of symptoms had been within the previous 12 months. Most patients were severely ill. The average HRSD rating at admission for the 94 patients who could be scored was 27.5; the remainder could not be scored because of incomplete information in the notes, apart from one patient who had been stuporose: 31% were within the range 19–24, 34% 25–29, 25% 30–34, and 10% more than 35, the highest score being 40. Serious suicide attempts had contributed to the presentation in 18 cases, and depressive delusions were prominent in the mental states of 44. Thus, these patients showed similar evidence of psychotic ideation to Post's, but were more severely ill and more likely to be called psychotic than Murphy's

Physical health. Nineteen per cent were judged to have no physical pathology and a further 22% only one quiescent problem; 13% had evidence of multiple quiescent pathology but no active problems, while an active health problem was present in 46%, which in 17% of all patients affected more than one system of the body. Six major body systems contributed to most of the pathology: cardiovascular (31 inactive and 9 active problems); central nervous system (7 inactive and 12 active); musculoskeletal (4 inactive and 11 active); respiratory (7 inactive and 7 active); genitourinary (6 inactive and 8 active) and gastrointestinal (6 inactive and 4 active).

Treatment prior to admission. Antidepressants, usually initiated by the GP, had been given to 47% prior to admission.

The index admission

This was relatively short for most patients: 20 were in hospital for less than one month, 56 for between one and three months, 18 for between four and six months, three for between seven and 12 months. Only three remained for more than a year, one of whom was still there at the end of the study.

With regard to treatments received, 45% had antidepressants and 48% ECT, either alone or in conjunction with drugs. The ECT course (always bilateral) averaged nine

treatments. The antidepressants were, in order of frequency, dothiepin, amitriptyline, and imipramine, with only four patients receiving other drugs, regardless of which of these was used, the daily dose averaged just over 100 mg (range 50–150 mg). When a change of treatment occurred, the most frequent reasons were either no response to a particular antidepressant (56%) or unacceptable side-effects or risks of physical health (37%).

The numbers of patients with each status at discharge (or at the end of study if not discharged), with the figures from Post's first cohort (in brackets) for comparison were: well, 69 (22); improved, 21 (65); little or no change, 7 (12); dead, 2 (1); not discharged, 1 (0). These two sets of figures differ significantly for the first three categories ($\chi^2=46.10$, d.f.=2, $P<0.001$), and show that our patients were more likely to be well at discharge.

Status one year on from the date of first admission

One patient had been lost to follow-up by this time, but detailed information for the rest was available. This interim appraisal has been included mainly to allow a comparison with the findings of Murphy (1983). Her categories of outcome have been used, and following her decision to exclude four patients who became demented during the year, we excluded one such case from our cohort. The majority of patients had done well: 58% of the whole sample were recovered and 65% of the subsample of 'new cases' (no previous illness since the age of 60) were well at one year. Within this group of recovered patients, there were 11 from the main sample and seven from the sub-sample who had experienced relapses during the year which had been detected and successfully treated by the service; 15% (13% of the sub-sample) were in relapse, but had spent a substantial proportion of time well, and were clearly differentiated from the 18% (17% of the sub-sample) who had continued to suffer from some symptoms, not always amounting to 'illness', throughout the year. Only 8% (5% of the sub-sample) had died (Table I). This represents a substantial significant difference from Murphy's findings, with a skew towards better outcome and fewer deaths.

Further analysis explores the suggestion that severity of symptoms and the presence of delusions at the time of presentation carry a particularly poor prognosis.

Severity. Four ranges of severity were earlier described for the 94 patients scored on the HRSD; the numbers in each of the four one-year outcome categories were calculated for each range of severity. There were no differences beyond chance expectations for the whole group $\chi^2=10.15$, d.f.=9, NS) or the sub-sample of 'new cases' ($\chi^2=10.72$, d.f.=9, NS). Six patients could not be scored for severity. Four of these had delusions and one had been stuporose; it could therefore be argued that these were 'severe' cases. The sixth patient refused to answer all the interviewer's questions and so could not be scored; his status at one year was 'well'. The outcomes at one year for the other five were: two well, one relapsed, one continuously ill, and one dead. Recalculating the data with these five patients included in the most severe band still yields non-significant results for all cases and 'new cases' (two of these five).

TABLE I
Status of patients one year from index admission

Outcome	All cases ¹ (n=98)		New cases only ² (n=77)		Murphy (1983) (n=120)	
	n	%	n	%	n	%
Well	57	58.1	50	64.9	44	36.7
Relapsed	15	15.3	10	13.0	23	19.2
Residual symptoms or continuously ill	18	18.4	13	16.9	36	30.0
Dead	8	8.2	4	5.2	17	14.1

1 Compared with Murphy's sample, $\chi^2 = 10.48$, 3 d.f. = 3 $P < 0.02$

2. Compared with Murphy's sample, $\chi^2 = 15.71$, 3 d.f. = 3 $P < 0.01$

TABLE II
Relationship between initial presence of delusions and one-year outcome for all cases (n=97) and new cases only (n=76)

Delusions	Outcome	Well		Relapsed		Continuously ill or invalided		Dead		Total	
		n	%	n	%	n	%	n	%	n	%
Absent	All cases	28	28.9	7	7.2	14	14.4	4	4.1	53	54.6
	New cases	24	31.6	5	6.5	10	13.2	3	4.0	42	55.3
Present	All cases	27	27.8	8	8.3	5	5.2	4	4.1	44	45.4
	New cases	25	32.9	5	6.5	3	4.0	1	1.3	34	44.7

Delusions. The definition used was that of the Present State Examination (Wing *et al.*, 1974), and only cases where delusional ideas had been unambiguously present were accepted. Simple ideas of hopelessness, self-depreciation and guilt arising out of depressed mood were not accepted, but both mood-congruent and mood-incongruent delusions were, provided the latter had occurred in the context of severely depressed mood.

The relative frequencies with which cases who presented with delusions were to be found in each of the four one-year outcomes groups (Table II) were calculated. These did not exceed chance expectations for the whole group ($\chi^2 = 3.54$, d.f. = 3, NS) or for the sub-sample of 'new cases' ($\chi^2 = 3.99$, d.f. = 3, NS). Moreover, of those patients who were well at one year, almost equal numbers had been deluded at presentation as had been free from such phenomena for both the whole group and the sub-sample. Thus, the initial presence of depressive delusions did not presage a poor outcome after one year.

The findings of the longer-term follow-up

These are presented in a style to facilitate comparison with Post's follow-up study over six years (1962) and follow-through study over three years (1972); mortality and change in diagnosis are considered independently of the outcome

for depressive symptoms. Six patients developed dementing illnesses, two experienced manic episodes, and four experienced paranoid symptoms not related to a mood abnormality. Thirty five patients died (27 women); two deaths were due to suicide, and one woman died of renal failure secondary to dehydration, soon after admission. The remainder were bronchopneumonia (six), myocardial infarction (six), malignancy (five, including three pancreatic), heart failure (four), stroke (two), and other causes (five). The cause of death of the remaining four patients could not be traced, but all but one (who had moved away) had been known locally, and death for reasons other than natural causes was most unlikely. The death rate was thus similar to that of Post's 1950 younger cohort, over six years, with a distribution of causes that included relatively less 'cerebral' pathology.

The outcome of depressive symptoms during life (Table III) is compared with Post's 1962 findings (see especially his Table IV), and with his 1972 study. The four patients about whom information was incomplete are excluded, although they were followed-up for an average of 21 months; these included one who was well throughout, two with a relapsing course, and one with depressive invalidism. Their inclusion does not significantly alter the data. Outcome is similar for all three cohorts, although the trend identified by Post for extremes of complete recovery or unremitting illness to be less common among patients admitted since the

TABLE III
The overall outcome for depression compared with the studies of Post

Dead	8	2	0	2	4

1. One-year status after Murphy (*n* = 98 to exclude one lost to follow-up and one with dementia); overall outcome after Post, i.e. status of depressed mood to end of study or death

introduction of antidepressant medication is even more apparent among our patients, although just failing to reach statistical significance (one-tailed test, $0.05 < P < 0.10$). Only seven patients experienced unremitting severe depressive symptoms, and of these four died within 12 months, and two had been referred to the psychogeriatric service as unresolved depression, despite treatment as in-patients by other psychiatrists. Of these elderly depressives, 93% were free from depressive illness for most of the follow-up period; in 22% this freedom was absolute, in 39% further episodes responded to treatment by full restitution, and 32% recovered but were less flexible and robust in mood than had been their former style, as well as sometimes experiencing circumscribed relapses of depression.

Patient characteristics and outcome

Demographic. There was no statistically significant relationship between age at admission, living alone, or civil status.

There was, however, an overall difference in the distribution of males and females over the four outcome groups ($\chi^2 = 9.42$, d.f. = 3, $P < 0.05$). This is largely accounted for by the finding that only one male patient experienced lasting recovery, in contrast to 21 of the women. Additionally, four of the seven members of the continuously ill group were men.

Past history. No association could be demonstrated between outcome and either past psychiatric history or a family history of depression. The seven patients who remained continuously ill had experienced more previous admissions than other groups, but this was not statistically significant.

Duration of illness. Only 18% had been ill for more than a year—similar to the 19% of Murphy's (1983) sample and substantially less than the 45% of Post's (1962) cohort.

Duration of illness of over 12 months did not predict a poor prognosis ($\chi^2 = 6.90$, d.f. = 3, NS).

Precipitating events. These have already been described. Neither their presence or absence nor any particular type of adverse event was associated statistically with any of the four outcome groups.

Suicide attempts. For the 18 patients who attempted suicide, this act was not associated with a poor prognosis overall.

Severity of depressive symptoms

The HRSD score at admission can be divided into two bands – 19–29 and 30–40 – to reflect two levels of severity. Excluding the six patients not ascertained for this variable, there were 62 patients with scores between 19–29 and 32 between 30–40. Of the latter, nine patients (28%) experienced lasting recoveries, ten (31%) had relapsing course, eight (25%) were left with residual features of depression, and five (16%) remained continuously ill. Compared with those with lower scores, the outcome differences are just significant ($\chi^2 = 8.36$, d.f. = 3, $P < 0.05$) and are largely accounted for by the finding that five out of six patients with group 4 outcomes (one patient from this group being unascertained) had Hamilton scores at first admission within the higher range of severity. The six excluded patients included none with 'lasting recovery', four with 'further episodes with full recovery', one with 'depressive invalidism', and one 'continuously ill throughout'. Five of these patients could reasonably be described as 'severe' (the outcome of the sixth being within the relapsing group with full recovery), but inclusion of them yields almost identical results ($\chi^2 = 8.44$, d.f. = 3, $P < 0.05$).

Delusions

The initial presence or absence of delusions can be related to each of the four overall outcome categories. As for the one-year assessment of this factor, there are no findings beyond chance expectations ($\chi^2 = 6.42$, d.f. = 3, NS). Of those with delusions at entry to the study, 25% remained well throughout, 34% subsequently had relapsing courses, 23% suffered some degree of depressive invalidism, and 18% remained continuously ill. It is interesting that six of the seven patients pursuing an unremitting course had presented with delusions, but the overall results do not suggest that the initial presence of delusions presages a poor long-term outcome for depressive illness.

Physical health

Health at admission. Statistical analysis will be confined to the six major body systems described earlier. Inactive health problems were distributed in a non-significant fashion among the four clinical outcome groups, and did not therefore predict any particular outcome. Likewise, there was no statistical association between outcome and the pathologies

of each individual body system taken separately, but the absence or presence of active health problems at presentation was not randomly distributed over the outcome groups ($\chi^2 = 12.29$, d.f. = 3, $P < 0.01$). Thus, of those without active health problems at first admission, the majority (70%) went on to clinical outcomes which were either of lasting recovery or of further relapses followed by full recovery. Only 3% of those with no active health problems at admission remained continuously ill with depression. From a different perspective, 20 of the 22 patients (91%) who experienced a lasting recovery had presented with no active physical pathology, while five of the seven (71%) who remained continuously ill with depression had at least one active health problem at first admission. The presence or absence of active health problems at entry was therefore associated with very poor and very good outcomes respectively.

Further health changes. Information concerning major health changes was available for 95 patients: 32 experienced serious changes in physical health during the follow-up period, and occurrence of these was highly associated with adverse outcome for depressive illness. Thus, 5% of group 1, 29% of group 2, 54% of group 3, and 71% of group 4 had experienced such change ($\chi^2 = 18.17$, d.f. = 3, $P < 0.01$). To assess the combined effects of initial health status together with further changes, a global health score was calculated for each case. Scores of 1 and 2 were ascribed for inactive and active health problems respectively at presentation, and a further score of 2 was added for a subsequent serious health change. A score of 0 or 1 indicated either no health problem or only an inactive one, 2 or 3 indicated moderate health problems, and 4 or more serious health problems either at entry to the study or acquired during the follow-up period. Of the 44 patients with scores of 0 or 1 ('absent or mild'), 35 (80%) had outcomes for depression within the best two groups. Of the 28 patients with scores of 4 or more ('severe'), 18 (64%) ultimately had outcomes of either depressive invalidism or unremitting depression, whereas those with 'moderate' scores experienced depressive outcomes little different from those expected by chance. Moreover, the numbers of cases with 'absent or mild', 'moderate', or 'severe' health problems represented within each of the four overall outcome categories did not conform to chance expectations. Of outcome group 1, 86% had 'absent or mild' health problems, decreasing to 42% for group 2 members, 29% for group 3, and only 14% for members of group 4. Correspondingly, only 5% of group 1 had combined health scores within the 'severe' range, compared with 24% of group 2, 46% of group 3, and 71% of group 4. These figures are significant ($\chi^2 = 27.14$, d.f. = 6, $P < 0.01$). The existence of adverse initial health and subsequent development of further physical pathology is therefore a powerful predictor of poor prognosis for depression.

Care provided after the index admission

Services provided by the psychogeriatric service. Two patients had no contact with the service after discharge. One

was discharged after persistent family interference with management plans, was subsequently readmitted under a different consultant psychiatrist, and at review, 52 months later, was clearly demented. The other patient defaulted from two out-patient appointments, and her progress until death 48 months later was traced via her GP.

Fifty-six patients either remained under supervision until their death (25) or were under supervision at the 1984 follow-up (31). Of these, one had remained in hospital throughout and 33 had one to eleven subsequent relapses; at other times, they had attended the day hospital or been seen regularly in the out-patient clinic or at home by a doctor, nurse, or social worker attached to the unit, with an average frequency of contact of three months.

The service discontinued its involvement with 42 patients. In 22, this was consequent upon an agreed plan that the GP would take on follow-up arrangements, in one case care was taken over by another specialist, and 19 simply moved away or repeatedly failed to attend the clinic, so that aftercare ended by default rather than by strategy. Nevertheless, these patients were followed up for 2-87 months (average 31), representing 46% of the potential follow-up time for this group. Thirteen of these patients (31%) had one to four admissions subsequent to the index admission and before being lost to further follow-up. In addition, outpatient or home visit contacts had been provided in the same way as described for the group successfully followed throughout.

Treatments for the mood disorder. Thirty-eight per cent were prescribed antidepressants on a prophylactic basis, either as a consequence of the index attack or of a subsequent relapse. A further 19% were prescribed antidepressants in response to relapses, but not maintained on them. Lithium was used in nine patients, but withdrawn from two because of side-effects. Thirty-six patients (including 12 from group 1) received either no psychiatric medication after the index admission or were in receipt of it only sporadically and without comprehensive supervision.

Comparison of Murphy's and Post's categories

A cross-tabulation (Table IV) shows the relationship between outcome at one year, as assessed by Murphy's method, and the longer-term 'course' outcome by Post's method. Of the 57 patients judged well after one year, 20 remained well, 28 experienced relapses (11 had occurred before the one-year cross-sectional analysis), and 9 suffered eventual chronic invalidism with or without relapses into illness. None, by definition, were continuously ill. Of those 15 in relapse at one year, ten remained characterised as 'relapsers' with recoveries to full health, and five were later chronic invalids; none, by definition, were continuously ill. Of the 18 described as 'continuously ill' up to one year, only one became so well that she could be classified as a relapser but able to regain full health; however, only three remained continuously ill in Post's terms, the remaining 14 suffering chronic invalidism but not to the extent of persistent illness. Four of the patients classified according to Post as 'continuously ill' had died within the first year, as had two

'chronically invalided' and two who had made a full recovery.

Discussion

The patients in this study were a highly selected sample of elderly depressives from the population at risk. They had been referred to a specialist service by other doctors who had made their own attempts to treat the mood disorder, and the specialist service itself felt that they were not treatable at home, whereas in general, two out of three depressives referred were managed without recourse to admission. Thus, they are likely to include more 'difficult' cases than those included by Post in his study of admissions in the 1950s, when the choice of effective drug therapy was limited and treatment might be stylised as either 'nothing' at home or admission for ECT. It is also possible that they were a more highly selected group than Post's later cohort of admissions, since his service at that time did not advertise availability of domiciliary treatment by the specialist team, although out-patient care was certainly practised and the range of physical treatments in use has not changed greatly. They represent one-third of the patients described by Murphy, who included all those referred from other services to the psychogeriatric team.

Post's cohort included younger patients and more men, but the patients in this study were very similar to those referred to the services studied by Murphy in terms of age, sex, social circumstances, duration of symptoms, and general physical health. We are less sure about social class, although the spectrum is probably similar, and we lack detailed information equivalent to Murphy's detailed enquiries about the presence or absence of a 'confidant'. Serious life events during the year before admission appear to have been more common in these patients than in those described by Murphy (1982, 1983).

It is interesting that the treatment used during their index admissions was very similar to that used by Post in the 1960s, ECT still finding a significant place and the antidepressants used being well-established drugs whose side-effects are well known and usually less limiting than is stated in the literature. On average, they spent less time in hospital than both of Post's earlier cohorts. During the index hospital stay, 21% of the group remained in hospital for longer than three months, compared with 41% of Post's 1960s cohort and 78% of his 1950s group.

The overall pattern of outcome at one year is dramatically better than that reported by Murphy: fewer patients had died and many more were well, while a particularly gloomy outcome for those who

presented with severe symptoms or delusions is not evident. The differences are so striking and the impact of Murphy's work has been so important that explanations are essential. It may be argued that our view has been rose-tinted, but this would not extend to differences in death rates, and is not in keeping with the longer-term follow-up. There can be only three explanations for our findings.

Our patients were intrinsically different and more likely to get better. This must be a possibility, though they shared many features in common and were certainly a 'more ill' group than the 'total referral' cohort in Murphy's sample. Nor can the differences be attributed solely to inpatient or outpatient status, for there was evidently no difference in outcome between those who were admitted and those who were not in East London (Murphy, 1983).

The services studied by Murphy were less effective than those in South Manchester. This too must be a possibility, although the styles of service are very similar and all are highly regarded; the range of treatments was the same, although possibly different use was made of them. It is easier to monitor response to treatment among inpatients, and it may also be easier to identify and treat relapses among patients who have been understood in depth while in hospital. Eleven such relapses that occurred to our patients during the first year after discharge were identified and successfully treated before 'one-year assessment'. No such occurrence was reported by Murphy; her comment on the 'poor' outcome cases that "remissions following treatment were often short-lived" begs the question as to whether or not those who relapsed were identified and energetically treated by the psychogeriatric service.

The only clear difference in treatment is that 48% of our patients received ECT (65% of those who were deluded), compared with only 16% (48% of the deluded) of Murphy's patients. We have remained convinced of the virtues of bilateral ECT (Benbow, 1985), but Murphy did not state which method was used. Since ECT is the most effective treatment for severely depressed patients with delusions, especially when antidepressants have failed to help them (Kantor & Glassman, 1977; Gill & Lambourn, 1979), it seems possible that some of Murphy's patients were under-treated in this respect.

There are weaknesses in the research assessment of outcome. Our own assessments must be viewed with some circumspection, as they depend on evaluation, based initially on our own records, of a situation some time in the past. However, these records are very detailed and informed by an in-depth knowledge of the patients over a prolonged period. In contrast, Murphy transposed her findings from

lengthy interviews to a number of standardised schedules; this has the apparent advantage of objectivity, but may not achieve accurate appreciation of the patients' experience. This is given credence by her comment that "The two categories 'continuously ill' and 'relapsed' appeared to be indistinguishable...". Such an observation is in keeping neither with Post's findings that many patients experience relapsing courses that do not preclude return to full health or to a status of invalidity considerably less than illness, nor with common clinical experience. An elegant research design and the utilisation of standardised schedules have much to commend them, but the data yielded may be less robust than first sight would suggest.

In contrast to the dissonance with Murphy's findings, there is considerable harmony between the pattern of outcome identified here in the follow-up study at 42-104 months and by Post at six years (1962) and three years (1972) respectively. This is despite the differences in the characteristics of the patients at entry. The shift away from the extremes of good and poor outcome for patients who were admitted in the 1960s rather than the 1950s is further accentuated in our mid 1970s to early 1980s admissions. This is understandable, since patients with the most easily treated states are likely to be excluded by treatment at home by their GP or the specialist team, thus avoiding admission. The reduction in the extreme of the poor prognosis group reflects a heartening response of many apparently difficult cases to sustained vigilance and persistence with effective treatments.

The presence of active physical illness at presentation and occurrence of new illnesses during the follow-up period are confirmed as the major factors prejudicing toward poor outcome. This is in line with previous studies (Post, 1972; Murphy, 1983) and emphasises the need for close collaboration between psychiatrists and both other specialists and GPs. However, most of the patients who suffered from unremitting mood disorder also had severe physical illnesses that were unresponsive to treatment. Carcinoma (two cases) and intractable conditions affecting the cardiac, respiratory, and haemopoietic systems were either present or subsequently developed in five out of seven such patients.

The finding that men did less well than women has not been noted previously, and it remains to be seen if this will become established as common to other groups of elderly depressives. Our men were, on average, more likely to be suffering from physical illnesses, and this may explain their excessive morbidity. Beyond these, no other factor stands out as being of prognostic significance. In particular,

delusions or severe depressive symptoms do not of themselves predict persistent morbidity, when confronted by appropriate and persistent therapeutic endeavour.

Murphy herself and Millard (1983) have suggested that her findings were similar to those of Post. However, direct comparison is not possible because the East London cases were not all admitted, and were assessed only 12 months after presentation, rather than followed through over a much longer period. In addition, the approach to assessment and the categories of outcome chosen by the two authors are quite different.

It is, however, of interest to compare the analyses of outcome for our patients using these two approaches. From the nature of the two extreme categories 'well' and 'continuously ill', it is predictable that the more time that is available, the fewer patients remain within them. Thus, some patients who were 'well' at 12 months suffered relapses from which they recovered to full health or a state of invalidism. Most patients with persistent symptoms for up to 12 months remitted to a state of invalidism, with or without episodes of illness, and one recovered entirely. The outcome categorised in this way at one year is therefore not a very helpful guide to outcome over a longer period, and it understates the importance of the intermediate outcomes of recurrent illnesses, with or without intercalated chronic invalidism, that become the rule by deterioration from full recovery and relapse from sustained illness.

Indeed, persevering with any sort of 'category' analysis of outcome has limitations. Post (1962) described a number of alternative approaches to this problem, but eventually returned to the original scheme (re-used later) which we have employed here to facilitate comparisons. The difficulty that categories designated 'continuous' are vulnerable to losing cases with the passage of time has been mentioned. A patient need only relapse for one month in a six-year follow-up to be placed in the same category as another patient who experiences 12 relapses with return to good health each time, and another who has a period of three months' good health followed by five years of unremitting illness. We encountered no such patient in actual fact, but there were some for whom the pattern of symptomatology changed so markedly that their inclusion in a particular category of outcome appeared unrepresentative of the real situation. For ten patients the change was quantitative, e.g. one man had five relapses in 30 months, but then remained well for the next 36 months. For another ten patients the change was qualitative, eight deteriorating from relapses with return to their former selves or to relapses

intercalated with chronic invalidism, while one made the opposite shift, regaining good health after a period of depressive invalidism. One woman, having been continuously ill from the date of admission for almost a year, began to improve and remained entirely well at follow-up – thus achieving a shift from continuously ill to continuously well (from the time of first recovery). Two patients who had experienced relapses and recovery to good health or invalidism over a period of more than three years then fell into psychotic illnesses that persisted for more than a year – to death for one and to the end of the study for the other. They had been well for large parts of the follow-up period, and thus remained classified among the relapsers with good outcome or invalidism.

These changes in the pattern of symptoms are clearly important, and it would be helpful to devise a classification capable of reflecting them. Interestingly, eight of the nine patients demonstrating a shift for the worse had experienced a new major physical illness. Of the eleven experiencing improved patterns of symptomatology, five achieved more supportive living conditions (one to live with a daughter, four to local authority residential homes), and three had been established on prophylactic medication (lithium for two and an antidepressant for the other).

While for the present purpose of comparison Post's scheme for the classification of long-term outcome is vindicated and supported, it must also be seen as inadequate in the case of many individual patients. A definitive classification of outcome could be achieved only by a prospective study of patients from inception to death, quantifying for this period the proportions of time during which patients had been completely well, intermittently well, depressively invalidated, or ill. Over the total further lifetime, numerous unpredictable factors will appear which affect prognosis, and prognosis of outcome may then be compared with other characteristics over the course of one, two, three, or more years to death.

Conclusion

It is clear that the prognosis for elderly patients suffering from depressive states which are severe enough to demand admission is far from gloomy. Most patients are helped by the exhibition of well tried and tested methods of treatment, offered in the context of a community-orientated psychogeriatric service that does not keep them in hospital for long periods of time, but is able to achieve responsible and responsive follow-up arrangements. Physical ill-health and male sex appear to make recovery from depressive symptoms less complete, but even the

most severely depressed, including those with delusional ideas, can regain normal mood. Collaboration with primary health care, other hospital specialties, and social services is essential in working with these patients, and is repaid by their response to treatment.

Much thought needs to be given to research methodology in this field; in particular, the prognosis for elderly depressives not admitted to hospital requires urgent evaluation. A modification of Post's

method of describing outcome would be helpful, and might be extended to facilitate comparisons with outcome for younger patients.

Exposure to Parental Alcoholism During Childhood and Outcome in Adulthood: A Prospective Longitudinal Study

W. R. BEARDSLEE, L. SON and G. E. VAILLANT

The effects of children's exposure to parental alcoholism was assessed using records from an existing prospective 40-year longitudinal study of working-class families: 176 men who had grown up with an alcoholic parent or parents were compared with 230 men without such exposure. Degree of exposure to alcoholism in the childhood family environment was highly correlated in later life with alcohol use, alcoholism, time in jail, sociopathy, and death, but not with increased rates of unemployment, poor physical health, or measures of adult ego functioning. Most of the impairments observed occurred in those subjects who actually developed alcoholism. Exposure to alcoholism in the family environment and family history of alcoholism independently contributed to the later development of alcoholism.

Alcoholism is a disorder that occurs in families (Cotton, 1979). The importance of genetic factors in this relationship has been well established, but the role of stressful environmental factors remains unclear. There is increasing concern that the children of alcoholics may be at risk for a variety of psychosocial impairments as a result of direct exposure to the parents' drinking behaviour. However, little attention has been directed at the quantitative examination of the degree of exposure of the child to the alcoholic parent or parents in the family environment during childhood. If environmental psychosocial factors do play a role in the occurrence of disorders in the offspring of alcoholics, then variability in exposure to such factors would be expected to affect offspring differentially; this paper examines the degree of exposure to parental alcoholism during childhood and its outcome during adulthood.

Previous studies

Investigators employing cross-sectional study designs have examined samples of children with parents who have presented for treatment for alcoholism. These studies demonstrated more deviant behaviour (Fine *et al.*, 1976), higher rates of psychiatric diagnoses (Herjanic *et al.*, 1977), more social problems (Chafez *et al.*, 1971), and more medical and psychosomatic symptoms (Nylander & Rydelius, 1982) in the children of alcoholics than in comparison subjects at the time of assessment. In terms of psychological functioning, children of alcoholics have been found to have poorer self-concept (Prewett *et al.*, 1981) and a lower sense of control on a locus of

control measure (Kern *et al.*, 1981) than comparison subjects. Various patterns of disrupted family functioning have also been observed (Wolin *et al.*, 1979; Wilson & Orford, 1978). The effects of such psychological factors on adult outcome is unknown.

Long-term impairments are evident in the children of serious alcoholics who have been followed over time. For example, in a recent follow-up study of men whose fathers had been diagnosed as alcoholic 20 years earlier (Rydelius, 1981), major impairments were evident in the areas of need for social assistance, alcoholism, social problems, sick leave from work, somatic complaints, and visits to a prepaid health clinic. Similar correlations were not found among the controls.

Genetic studies using adopted-away designs concur in finding a significant genetic component in the transmission of alcoholism. In several of the studies (Cadoret *et al.*, 1980; Goodwin *et al.*, 1973, 1974, 1977a, 1977b), data indicated that environmental factors did not play a large role. In others (Cloninger *et al.*, 1981; Bohman *et al.*, 1981), two distinct types of inheritance were postulated: one purely determined by genetic factors, and the other determined by an interaction of the milieu and a genetic susceptibility to alcoholism (termed 'milieu limited'). At the present time, it is not known which of these two is correct.

Longitudinal studies of subjects not identified initially because of alcoholism, but involving some subjects who develop alcoholism, present an opportunity to examine the antecedents of adult alcoholism. Studies of youngsters already identified in childhood as deviant have been followed by McCord

& McCord (1960) and by Robins (1966). They demonstrate that such antisocial youths, coming from homes where parents abuse alcohol and have a number of problems associated with social disadvantage, develop both alcoholism and sociopathy more frequently than comparison subjects. McCord & McCord postulated personality factors and family variables as the key to understanding later alcoholism; Robins placed more emphasis on genetic factors.

Longitudinal studies of subjects selected for health at the time on entry have particularly examined the issue of whether there is a specific personality trait, or cluster of personality traits, that predisposes to alcoholism, following the suggestion (McCord & McCord, 1960; Jellinek, 1960) that such personality factors exist. The weight of the evidence from longitudinal studies is against this (Beardslee & Vaillant, 1984; Vaillant, 1980; Kammeier *et al.*, 1973).

A sample of men recruited by Glueck (1950, 1968) as comparison subjects for the study of delinquents have proved particularly valuable in understanding both the course and the aetiological components of alcoholism, because of its size, the length of the prospective longitudinal follow-up, and the relatively high proportion of alcoholics. The natural history of this disorder has been described (Vaillant, 1983), and the process of recovery was carefully delineated by Vaillant & Milofsky (1982a). Investigators have separated the antecedents of several overlapping adult outcomes in this sample: poor mental health, sociopathy, and adult alcoholism (Vaillant & Milofsky, 1982b). Using multiple regression techniques, four childhood variables (childhood environmental strengths, boyhood competence, childhood emotional problems, and IQ) significantly predicted adult ratings of mental health 33 years later. Four other variables predicted sociopathy: delinquent parents, multi-problem families (families with lack of cohesion and lack of affection or supervision by mother or father), poor infant health, and premorbid antisocial personality. Finally, four more variables were significantly associated with adult alcoholism, but not with sociopathy or poor mental health; alcoholism in parents, alcoholism in ancestors (excluding parents), alcoholism in heredity (a combined scale of the two previous categories), and ethnic background.

Our current study is a natural extension of previous explorations of Glueck & Glueck's sample, and examines the effect of the child's degree of exposure to the parents' alcoholism. We predicted that varying degrees of exposure to parental alcoholism would affect blindly related data of adult outcomes. Exposure to parental alcoholism includes

both the amount of drinking and the disruption of family functioning due to alcoholism, in such areas as discord, unavailability, lack of financial support, and family violence.

We specifically examined the following hypotheses:

1. Within the entire sample, increasing amounts of exposure to alcoholism and its concomitants in the environment of the developing child will be correlated with higher rates of general impairment in adulthood.

2. Increased exposure to alcoholism in the environment will lead to increased alcohol use, increased abuse of alcohol, and increased sociopathy in adulthood.

We examined the effects of the degree of exposure to parental alcoholism on the age of death in the two groups; the number of men who had died was expected to be too small to be significant, and thus no specific hypothesis was formulated.

In addition, an exploratory analysis was undertaken to examine the relative contribution of an extensive family history of alcoholism and of exposure to environmental alcoholism in terms of the outcomes in adulthood.

Method

Sample

The subject sample (Vaillant, 1983; Glueck & Glueck, 1968; Glueck & Glueck, 1950) consisted of 456 inner city youths chosen by the Gluecks as control subjects in their prospective study of juvenile delinquents. Between 1940 and 1945, these men were studied in junior high schools as non-delinquents. They had been carefully matched with respect to IQ, ethnicity, and residence in high-crime neighbourhoods with 500 Boston youths who had been remanded to reform school. Almost all of the men were from blue collar homes, and 31% of their parents met the Hollingshead-Redlich Social Class V criteria (unskilled workers in derelict housing with nine or less grades of education). Of the boys' parents, 61% had been born in a foreign country. All the subject families were Caucasian, except for one Oriental family.

At the time of the original study, the boys and their parents and teachers were individually interviewed. For all first-degree relatives, public records were searched for an excess of alcohol or criminal behaviour and mental illness. Attrition over the years has been modest. The majority of subjects were re-interviewed at ages 25 (circa 1955), 32 (circa 1962), and 90% of them at 47 (circa 1977).

Of the 456 men, 176 had had some exposure to alcoholism. For the purpose of this investigation, these 176 men were defined as a sample exposed to alcoholism and then rated using the Exposure in Childhood to Alcoholism in the Family Environment scale (ECAFE), while the remaining men served as non-exposed comparison subjects.

Independent variables assessed

Clinicians blind to all information after adolescence reviewed social service records and interviews with each boy, his parents, and teacher, and rated each subject on the following premorbid variables:

IQ: Each subject was administered the Wechsler-Bellevue Intelligence Test on entrance to the study.

Social class: Using the five-point classification scale devised by Hollingshead & Redlich (1958), each participant was rated for social class on the basis of his parent's education, father's occupation, and familial residence.

Alcohol abuse in relatives. This scale (Vaillant & Milofsky, 1982b) reflected alcoholism in the child's heredity (in known ancestors prior to 1945). Parents and siblings were included as well as other first- and second-degree relatives, if known. If reliable judgement was not possible, due to ambiguous or absent familial data, a rating was not made. The scale points employed were: 1 = no evidence of alcoholism in the family; 2 = one relative with minor evidence of alcoholism (two convictions for alcoholism, mention of alcoholism in official records, or strong suspicion in the case record that was compiled from family interview and multiple social service agency reports); 3 = two relatives with minor evidence of alcoholism or one relative with major evidence (defined as two or more criteria for minor evidence and evidence for chronicity); 4 = three relatives with minor evidence or two relatives with major evidence.

The ECAFE scale

The data base for rating the Exposure in Childhood to Alcoholism in the Family Environment (ECAFE) scale included all material collected on the child and his family until age 17 in the existing Glueck records. It included direct interview material, family interviews, school records, and psychological tests. The scale and a manual defining the scale points were constructed by detailed review of a series of records to identify variables that could be reliably rated, were expected to be harmful to the developing child, and were likely to be associated with alcoholism. Greatest weight was given to extent of parents' drinking, with less weight for associated problems.

For father, mother, stepfather, and stepmother, separate ratings were made of the extent of alcoholism in the family environment to which the child was exposed. Ratings of 0 were made when there was no evidence of alcohol abuse whatsoever, or if the subject had suffered from alcoholism but not during the child's lifetime. Ratings of 2 were made when there was some evidence of alcohol abuse (possibly involving bootlegging charges, or arrest for violation of liquor laws) but such evidence was not extensive in the records. Ratings of 4 were reserved for situations in which alcoholism was severe and long standing, having occurred during at least several years of the child's life. Criteria included references to chronic alcoholism in the material from the raters, indications that home and work life were severely affected by the subject's drinking, and a record of more than five arrests for drinking behaviour.

In addition, individual ratings of either 0 or 1 were made for six types of family behaviour harmful to children: fre-

quent absence of the parent (not due to employment or military service); fiscal irresponsibility of the parent; physical abuse of the spouse or the child by the alcoholic parent; and two ratings of disorder – general discord and specific parental marital discord. It is not possible to say that every episode of these six types of behaviour occurred because of a specific episode of drinking, the intent was to code them when they occurred in association with overall drinking behaviour. They were chosen as six clear behaviours which were known from general review of the literature of alcoholism in families to be associated with alcoholism, were also known to be harmful to children during their development, and which could be rated on the basis of 40-year old records.

Finally, a senior clinician reviewed all the records in order to weight the time interval of exposure of the child to the parents' alcoholism. This variable was given a score of 0, 1 or 2 and was used primarily to give added weight to families in which there were long periods of exposure to alcoholism (greater than five years), in comparison with families in which alcoholism had been limited only to a relatively short period of the child's life.

Reliability was examined by means of a blind paired rater trial, using 25 rated records before the ratings were made, and was found to be above 0.60 for all except 'drinking parent financially irresponsible', for which it was 0.50.

Using this rating process, scores on the ECAFE scale ranged from 0-15. The median score for the exposed group was 7, the mean score 7.1, and the standard deviation 3.06.

Outcome variables: overall adult functioning

On the basis of two-hour interviews at age 31 and 47, and of a review of recent mental health and arrest records, clinicians blind to all data gathered before age 31 rated the men at age 47 (± 2 years) on the following variables.

Overall adult functioning

Percentage of time unemployed. This was taken as the percentage of time from entry into the study until the time of measurement unemployed.

This was rated using the overall health Health Sickness Rating Scale (HSRS) (Luborsky, 1962). On the basis of graded ratings, HSRS places individuals along a 100-point continuum that ranges from total institutional dependency (0-10) to exhibition of multiple manifestations of positive mental health (90-100).

Social competence. This 25-point scale (Vaillant & Milofsky, 1980) measures the capacity for human relations; ratings reflect relative success in accomplishing eight difficult tasks of adult object relations. One task each reflected enjoyment of children, family of origin, and workmates; three tasks reflected friendship networks, and two tasks reflected participation in group activities. Marriage is excluded.

Mood disturbance. This was rated a measure of mental health at time of interview. Mood ratings were made on a four-point scale. 1 = excellent; 2 = good; 3 = fair, moody; 4 = depressed, blocked.

Alcoholic/sociopathic variables

Alcohol dependence (DSM-III). A three-point scale defined by DSM-III (American Psychiatric Association, 1980) and reflecting the medical model for diagnosing alcoholism was used: 1=no alcohol abuse; 2=alcohol abuse; 3=alcohol dependence (evidence for alcohol abuse and tolerance or withdrawal symptoms from alcoholism).

Time in jail. This was expressed as the percentage of time the subject had spent incarcerated since age 18.

Sociopathy. This rating was based on the 19 criteria used by Robins (1966) for the diagnosis of sociopathic personalities. Presence of five or more criteria led to the diagnosis of sociopathic personality.

Problem drinking scale (PDS). This scale (Vaillant, 1980) was an equally weighted 16-point scale devised to combine the emphasis of DSM-III (American Psychiatric Association, 1980) on the physiological dependence and the emphasis of the Cahalan scale (Cahalan, 1970) on social deviance. The scale depends on objective alcohol-related problems (e.g. blackouts, arrests, medical complications of alcohol abuse) and gave double weights for alcohol problems that occurred frequently. Men with one or no symptoms on the scale were by definition social drinkers; men with four or more symptoms were defined as alcohol abusers.

Statistics

In order to examine the effects of increasing amounts of environmental exposure to parental alcoholism using the ECAFE scale, Kendall's tau was used, as both the outcome variables and the dependent variables contained ordered categories. In order to examine the inter-relationship of alcoholism in heredity and the family environment, two different statistical techniques were used. Firstly, the analyses of the ECAFE scores compared with adult outcome were repeated specifically for those subjects who had

high scores (3 or 4) on the 'alcohol abuse in relatives' scale, in order to separate, as much as possible, the effects of family history of alcoholism from environmental exposure. Secondly, stepwise multiple regression techniques were used to explore further the relationship between the 'alcohol abuse in relatives' and ECAFE scales. IQ and social class were included as covariates. The regression analyses were carried out without ordering the variables before entry.

Results

Although attrition had been modest, not all men had received all measures in the project. Samples sizes thus varied between categories of outcome

Overall functioning

For four measures of overall functioning in adult life (percentage of life unemployed, HSRS rating, social competence, and mood disturbance), increasing amounts of exposure to alcoholism did not result in increased disorder, when compared with the non-exposed group of men at follow-up. A summary of the mean group scores for four levels of ECAFE exposure is given in Table II. There was a difference between the extremes of exposure for only one variable: years unemployed.

Alcoholic and sociopathic outcomes

A strikingly different picture emerged when the outcomes of DSM-III diagnosable alcoholism, time in jail, sociopathy, and problem drinking were analysed (Table I). In each area, significant associations were found between increasing levels of exposure to alcoholism in the child's family environment and poor outcome.

A diagnosis of DSM-III alcohol dependence was received by 71 men in this sample. Of these, 26 came from the sample

TABLE I
Relationship of childhood exposure to alcoholism and adult outcome: mean score and statistical association

ECAFE range	Time unemployed: %	HSRS	Social competence	Mood disturbance	DSM-III Alcohol dependence	Time spent in jail	Sociopathy	Problem drinking
0	8.80	74.82	5.99	2.46	1.36	1.32	2.06	2.84
1-4	4.81	75.77	5.91	2.32	1.60	1.45	2.50	3.90
5-7	8.86	73.37	6.16	2.44	1.70	1.60	3.00	4.72
8-9	11.54	74.17	5.82	2.38	1.81	3.00	2.76	5.54
10+	16.00	73.57	6.48	2.43	1.91	1.98	3.51	5.49
Kendall's tau	0.028	-0.34	0.028	-0.03	0.207	0.08	0.169	0.220
P	0.235	0.194	0.248	0.26	0.00001	0.03	0.00001	0.00001
Total n	419	377	383	390	398	430	429	441

with no exposure ($n=280$, i.e. 9%), while 45 came from the sample with an exposure to alcoholism in the family environment ($n=176$, i.e. 26%). In terms of sociopathy, 19 (7%) men received a definite diagnosis in the non-exposed group, while 31 (18%) did in the exposed group.

Age of death

Although the numbers were modest, there was a higher death rate in those exposed to alcoholism in childhood (Table II). Causes of death present no clear pattern. Most of this effect occurred in the older age-group: 10 men had died before age 35 (4%) in the non-exposed sample, and four (3%) in the exposed sample. After age 35, 17 (7%) had died in the non-exposed sample, while in the exposed sample 25 (15%) had died.

Nature of individuals seriously affected

The effects of parental environmental exposure to alcoholism on outcome were then examined, excluding the cases with a DSM-III diagnosis of alcohol dependence (71 cases), and the cases where no diagnosis was possible (57). It was then possible to examine whether the main effects in this sample occurred in those individuals with severe alcoholism, or whether such effects were more evenly distributed throughout the entire exposed sample. When the cases of diagnosable alcoholism are removed in this way, the results for the overall functioning measures are not significant, as before. For the alcoholic and sociopathic outcomes, significant effects are not present for any of the variables except problem drinking behaviour (Table III). Most of the effects of environmental exposure were thus due to the relatively few individuals who were seriously affected.

Relative contributions of family history and childhood environmental exposure

For the sample with high (3 or 4) scores for family history of alcoholism, more exposure to parental environmental alcoholism resulted in more pathology. There is a significant association of ECAFE score with sociopathy, DSM-III diagnosis of alcoholism, problem drinking, the overall health rating, cumulative unemployment, and time in jail, but not mood disorder, defences, or object relations (Table IV). This is similar to the previous analysis (Table I),

although some variables of overall adult functioning now reach significance.

These findings were explored using multiple regression techniques (Table V). Three main outcomes were examined: DSM-III alcoholism, sociopathy, and problem drinking.

<i>Dependent variable</i>	<i>Independent variable¹</i>	<i>Beta weight</i>	<i>t</i>	<i>p</i>
DSM-III alcohol dependence	Heredity	0.28	4.7	0.00001
	ECAFE score	0.21	4.2	0.00001
Sociopathy	IQ	-0.96	-2.0	0.04
	ECAFE score	0.21	4.6	0.00001
Problem drinking	Heredity	0.19	4.2	0.00001
	ECAFE score	0.23	5.0	0.00001

¹ IQ, heredity, ECAFE score and social class of origin were all tested for each dependent variable; only significant results are shown

Two variables shown to be important in long-term outcome from the overall longitudinal follow-up work were included: social class of origin and IQ. For all three dependent variables (alcoholism, sociopathy, and alcohol use), childhood familial environmental alcoholism made a significant independent contribution. Family history of alcoholism contributed to DSM-III alcoholism and to problem drinking, but not to sociopathy. IQ is related to sociopathic outcome but not to the other outcomes, while social class of origin has no effect.

Discussion

The persistent major effects of increasing degrees of exposure to alcoholism in the family environment on the developing child are in the areas of adult alcoholism and sociopathy. The main hypotheses of our study are strongly confirmed for the outcomes of problem drinking, DSM-III diagnosis of alcoholism, time in jail, and sociopathy, but not for the general indices of overall adult psychological functioning. Multiple regression analyses, and analyses of a sub-set of the sample including all individuals with extensive family histories of alcoholism, demonstrate that both alcoholism in the environment of the developing child and a family history of alcoholism make independent contributions to poor adult outcome.

The main effects of exposure to parental alcoholism in childhood occurred largely in the relatively small group of individuals who develop alcohol abuse; when alcoholic subjects were eliminated from the analysis, the differences between subjects exposed to alcoholism and those not exposed disappears. This, in combination with the lack of effect on major variables of adult functioning (such as overall physical and mental health, years unemployed, and mood), suggests a considerable resiliency in terms of

overall functioning in the children of alcoholics who do not develop alcohol abuse, although such a thesis must be advanced with caution. The most important caveat is that our follow-up sample was 47 years-old at the most recent assessment, and had been initially selected as a control group. The affliction of parental alcoholism may have affected the individuals' lives in ways not evident in these objective outcome variables. Moreover, a common result of parental alcoholism is delinquent adolescents, but this sample was specifically selected for non-delinquency.

The importance of a longitudinal perspective is emphasised by findings from the examination of the age of death. Men whose parents were alcoholic and who were exposed to alcoholism in growing up have significantly higher death rates, but this pattern emerges only in men over 35. No conclusion can be reached at this point about why there is a higher death rate: it is known that the death rate of alcoholics is two to three times that of non-alcoholics, but only 18% of these deaths occurred in men who were alcoholic.

A central issue of interest is the relative weights of genetic and environmental influences in the aetiology of alcoholism in this or other samples. This study was not designed to separate genetic from environmental influences; nor is it possible to do so within the limits of the data, as the two effects occurred together. It may be possible to do it in future years, using techniques of mathematical modelling and results from studies under way.

The relationship of these data to the findings of wide ranging impairments in children of alcoholics in many of the cross-sectional studies deserves comment. Most such reports involve youngsters whose parents presented for treatment of alcoholism in clinics. These samples were assessed in adolescence, not mid-life. Moreover, some children in

the cross-sectional studies who were already delinquent would not have been included in our study. Most importantly, it must be emphasised that we have used blindly rated, objective behavioural outcomes 30 years after the period of parental exposure. This means that many other factors influencing overall mental health functioning, such as quality of marriage, employment, and physical health since childhood, have intervened. We also did not specifically examine such psychosocial factors as self-esteem, family rituals, or other psychodynamic factors related to alcoholism in the cross-sectional examination in childhood.

Limitations

It was not possible to follow all individuals over this long time period with all measures. The tables give the number of individuals for each calculation, and hence give some idea of the number of missing values.

Attrition was more common in those individuals with high ECAFE scores. There was little difference between the exposed and non-exposed groups in terms of missing data on the dimensions of sociopathy, alcoholism, alcohol use, or years unemployed. In 34 cases, attrition limited information on overall mental health rating (HSRS) and social competence, with more data missing from the high-exposure group. If anything, the effects of environmental exposure would be likely to increase in these dimensions, had the additional individuals been present.

It was not possible with this data set to characterise accurately the total length of alcoholic episodes or the exact timing in relation to the child's life, as the initial assessments were conducted in the men's adolescence, and such information in detached diagnostic terms was not elicited. In this sense, the ECAFE scale represents a compromise. In the interval between assessment and follow-up, other variables may have played a role in alcoholism. These factors, such as peer relationships (Jessor & Jessor, 1975) and occupation (Plant, 1979), were not examined as causes of alcoholism in adulthood.

It could be argued that the family environmental alcoholism scale really taps two dimensions: pure drinking behaviour; and family discord and parental irresponsibility. However, since the first is so often highly confounded with the second in the actual experience of children in these families, and the focus

of this investigation is the child's experience, we did not separate them.

The study focused on relatively discrete outcomes in the offspring and the quantification of a single major parental variable (familial exposure to alcoholism and its effects.) We did not attempt to examine various factors within the child which might lead to increasing amounts of alcoholism. Such factors as adaptational capacity, resiliency, early and persistent use of alcohol, drugs, or smoking, and early aggressive behaviour (Kellam *et al*, 1980), all present intriguing areas for study.

Implications

This study emphasises specifically the importance of consideration and further study of the child's contact with and exposure to parental alcoholism in combination with genetic factors. Those families in which parental alcoholism has been long standing and in which there is an association between alcoholism and various kinds of family disorganisation and discord are those in which the youngsters are at highest risk in the long term. There is a need for intervention as soon as possible in the youngsters' lives, and in the parents' course of disorder, because the greater the degree of exposure, the greater the effect.

Conclusion

In spite of the negative effects of growing up in a family with alcoholic parents, the overall conclusion is hopeful. The majority of youngsters in this sample functioned similarly to those in the non-exposed group during adulthood, in spite of the severe alcoholism and discord in the families in which they grew up.

In contrast to the frequency with which poor outcomes such as chronic depression or 'borderline personality' appear to be associated with a history of parental alcoholism, in this study parental alcoholism did not reflect an increase at age 47 of non-alcohol related psychiatric disability.

Marital Adjustment, Intimacy and Needs in Female Agoraphobics and Their Partners: A Controlled Study

W. A. ARRINDELL and P. M. G. EMMELKAMP

Female agoraphobics and their partners were compared with three groups of control couples (non-phobic female psychiatric patients and their husbands, maritally distressed couples, and happily married couples) on measures relating to marital adjustment, intimacy, and needs. Neither agoraphobics nor their partners rated their marriages as more maladjusted or unpleasant than non-phobic psychiatric patients or their partner controls. Instead, agoraphobics and their spouses were found to be more comparable to happily-married couples than to maritally-distressed controls. Non-phobic psychiatric patients and their partners were generally found to rate their marriages as being as distressing and unpleasant as those of maritally distressed controls.

It has been suggested that the relationship of agoraphobic patients with their marital partner may be of critical importance in the precipitation, maintenance, and perpetuation of the agoraphobic symptoms. A number of authors (Webster, 1953; Fry, 1962; Lazarus, 1966; Hand & Lamontagne, 1976; Goodstein & Swift, 1977; Chambless & Goldstein, 1980; Barlow *et al*, 1981; Goodstein, 1981; Hafner, 1977, 1982; O'Brien *et al*, 1982) have pointed out that agoraphobia may more suitably be described in terms of both an interpersonal, particularly marital, conflict and an intra-psycho conflict. However, in comparison with the emphasis that has been put on the possible role of marital difficulties in the aetiology of agoraphobia, hardly any methodologically sound studies have been conducted with the aim of scrutinising whether and to what extent the marriages of agoraphobics differ from those of controls.

Goldstein (1973) concluded, on the basis of case-history reports, that agoraphobics can be typified at the time of symptom formation by four characteristics: (a) female; (b) in a close relationship, usually married; (c) feeling a strong urge to escape this relationship; and (d) feeling trapped in the sense that the patient is afraid of or intimidated by possible alternatives. He argued that conflict created by an unhappy marriage is a constant situation from which escape can only be through psychological avoidance responses, and proposed that "agoraphobic symptoms are often the result of such psychological avoidance behaviour in conflict situations that seem unsolvable". Thus, in his view and that of Chambless & Goldstein (1980), agoraphobics wish to flee the marriage but cannot do so because of their dependency and fears of being alone.

Most of the available studies emphasising the importance of quality of marriage in the aetiology of agoraphobia (e.g. Webster, 1953; Fry, 1962; Goldstein, 1973; Symonds, 1973; Hudson, 1974; Shafar, 1976; Melville, 1977; Hafner, 1981; Holmes, 1982) are based on confusing methodologies, characterised by any of the following aspects: (a) lack of adequate control groups; (b) unspecified or inadequate operationalisation of the criterion measures (e.g. marital adjustment, intimacy, or quality); (c) the use of interview techniques of unknown reliability and validity; (d) retrospective description of clinical anecdotal material; (e) use of samples that are biased, inadequately specified as to diagnosis and outcome, and whose patients have been selected and treated by the authors themselves; and (f) lack of distinction between the sexes. Despite these shortcomings, these studies have provided an abundance of comments concerning the quality of marriage in agoraphobics and their partners.

On the basis of data obtained from an unspecified number of female, mainly agoraphobic patients, Fry (1962) suggested that the husbands' statements indicate doubt about their commitment to the marriage and that they were also characterised by their jealousy and occasional impotence. Usually, the marriage was miserable and the couple distant and discontented, the symptoms functioning to keep the couple united in a compulsory marriage. Though the discontented patient may at times indicate some desire for an extramarital relationship, her phobia prevents her from getting involved with other men.

Symonds (1973) selected three female patients suffering from intense fear of travelling and of being alone, from records of a larger group of patients with

phobias ($n=12$) gathered over a period of 20 years. A picture emerged of the patients as being helpless and dependent, and unable to handle even the slightest friction that occurs between two people who live together. Symonds argued that the many psychosomatic symptoms observed were an expression of repressed anger towards the partner, and that the phobias are one of the ways of dealing with their repressed feelings.

Hitherto there has only been one controlled study examining the quality of agoraphobic marriages: Buglass *et al.* (1977) compared agoraphobic housewives and their spouses with normal control couples in terms of domestic activities (i.e. the execution of specified family tasks), decision-making in a number of areas, and manifest interaction ratings (assertion-compliance and affection-dislike). The most striking feature of the comparison between the two groups of couples was their similarity with respect to these measures.

The aim of the present study was to investigate the quality of the marital relationship of agoraphobic patients and their partners by comparing their marriages with those of three groups of controls: non-phobic psychiatric patients and their partners; maritally distressed couples; and non-distressed (happily married) couples.

Clinical anecdotal studies suggested that agoraphobics as a group would: (a) report their marriages as more distressing or maladjusted, both maritally and sexually; (b) indicate greater needs for interpersonal contacts and intimacy (not necessarily sexual or erotic) outside their marriages; (c) appear to be emotionally more dependent on their marriage partners and show greater tendencies towards centredness on their partners; and (d) exhibit greater avoidance of communication and greater lack of intimate communication than non-phobic psychiatric and maritally non-distressed controls (e.g. Webster, 1953; Fry, 1962; Goldstein, 1973; Symonds, 1973; Melville, 1977; Holmes, 1982). As a consequence, agoraphobics should appear to be more comparable to maritally distressed subjects than to either non-distressed or non-phobic psychiatric controls on measures of marital adjustment and intimacy. Furthermore, as compared with controls, the partners of agoraphobics should show evidence of greater degrees of felt distress, due to the possible intention of the patients to perform extramarital acts with a sexual component (e.g. Fry, 1962). In view of the general picture of the spouses of agoraphobics as being persons who are not dissatisfied with their marriages—i.e. the spouses might have vested interests in maintaining the phobia (e.g. Fry, 1962; Hudson, 1974)—no further specific differences were

hypothesised for comparisons involving the partners and controls.

The above hypotheses suggest that an examination of similarity of marital ratings within and across couples might also prove illuminating.

To control for the possible confounding effect of gender on the self-report of the quality of marriage (e.g. Schumm *et al.*, 1981), only female psychiatric patients were considered here. Surveys from the literature on background factors affecting the self-report of marital quality (Lewis & Spanier, 1979; Dominian, 1982; Markman *et al.*, 1982; Birtchnell & Kennard, 1984; Filsinger & Wilson, 1984) suggested a number of other variables which may be of importance: age at the time of marriage, education, occupation, race, religiosity, and rate of conception of children. In our analysis of data, the influence of these factors was accounted for. Finally, since no study investigating the present matter would be complete without considering the issue of desirable responding (Hansen, 1981), two measures were taken to reduce its impact as much as possible.

Method

Subjects and procedures

Thirty agoraphobic, 11 non-phobic psychiatric, 14 maritally distressed, and 38 non-distressed (happily married) females and their partners took part. Demographic data for husbands and wives are given in Table I.

The agoraphobic out-patients participating in the present study were females who were referred to our department for treatment between October 1980 and May 1983. Their selection was based on three main criteria. Firstly, the subjects had to meet the DSM-III (American Psychiatric Association, 1980) criteria for agoraphobia as a major disorder. Secondly, the agoraphobia had to be persistent, severe, and result in consistent avoidance of the phobic situation. To determine this, 30-minute clinical interviews were conducted to obtain clear evidence of whether work or social life-style were significantly affected by the agoraphobia. Thirdly, subjects had to score at least 17 on the Agoraphobia sub-scale of the Marks & Mathews (1979) Fear Questionnaire (FQ) (mean = 30; range = 17–40).

Three control groups of couples were used. The first consisted of female non-phobic psychiatric patients who were awaiting treatment, on an out-patient basis, after their initial contact with the clinic. Their husbands also participated in the study. The patients were selected on the basis of the following criteria: the subject was judged both by the clinical team and by the researcher not to be suffering from a clinical phobia, and the subject had to score below 17 on the FQ Agoraphobia sub-scale. The second group of controls were randomly drawn waiting-list maritally distressed or conflict couples who were self-referred for marital difficulties to a non-university community mental health centre. To ensure that there would be no overlap with other couple groups, an additional selection criterion was that

both husband and wife be judged by the clinical team and by the researcher not to be suffering from a clinical phobia. They were also found to score less than 9 on the FQ Agoraphobia sub-scale. Subjects from the third control group (maritally non-distressed couples) were individuals considering themselves to be happily married, and were solicited from newspaper advertisement for participation in a project on 'communication in marital relationships'. Inclusion criteria for this group, applied to both partners, were: (a) no prior history of in- or outpatient treatment for psychiatric disorders; (b) judged not to be in need of treatment for psychiatric difficulties; (c) scores below 17 on the FQ Agoraphobia sub-scale.

The following criteria were used across all groups: (a) minimum age of 18 years; (b) married and cohabitating with the spouse for at least one year; (c) Dutch-born Caucasian subjects (i.e. ethnically/racially non-mixed couples).

Clinical interviews were conducted in our department after completion of the questionnaire set described below, no volunteering couples were excluded from the study on the basis of these interviews. Since none of the eligible agoraphobic subjects failed to volunteer, they can be considered representative of the female married patients treated in our department in terms of demographic variables and the degree of severity of the agoraphobic complaints presented.

For all subjects awaiting treatment, it was required that they participated prior to its start.

All subjects were tested individually, to prevent the couples from completing the questionnaires together and discussing the items. Standard instructions for the questionnaire set were given to each subject. All questionnaires were completed anonymously, and confidentiality of the subjects' responses was emphasised. To further minimise 'socially desirable' responding, honesty in responses was emphasised, which Eysenck *et al* (1974) have shown to significantly reduce dissimulation. In addition, a measure of social desirability was appended to the questionnaire set, to have some means of evaluating its impact.

Measures

The following scales were utilised.

(a) The *Maudsley Marital Questionnaire (MMQ)* (Crowe, 1978; Cobb *et al*, 1980) in a version adapted for use in the Netherlands by Arrindell *et al*, (1983a). The MMQ is a short 20-item scale relating to marital, sexual, and general life maladjustment (function and interaction). The scale is also known as the Modified MMQ (Cobb *et al*, 1984).

(b) A *General Marital Dissatisfaction* and a *Sexual Dissatisfaction* scale: satisfaction is defined in the sense of learning theory, as the frequency with which one experiences the interaction with one's partner as pleasant (positively reinforcing).

(c) A number of *Communication* scales, referring to intimate communication, destructive communication, *discongruent* communication, and avoidance of communication; these deal with the quality of perceived communicative behaviour in the marital relationship.

(d) The *Need for Interpersonal Stimulation* scale, as a

measure of the degree of an individual's need for regularly experiencing new personal contacts.

(e) The *Need for Intimacy* scale, as a measure of one's need for intimate personal (but not necessarily sexual or erotic) contacts with people other than the marital partner.

(f) An *Emotional Dependency* scale, as a measure of the degree to which one feels oneself emotionally dependent on one's partner.

(g) An *Exclusive Partner-Centredness* scale, as a measure of the degree to which one experiences an exclusive directedness or focus on the marital partner as positively reinforcing.

(h) An *Intentional Extra-Marital Involvement* scale, as a measure of the degree of felt distress from possible intents, ideated by oneself, of one's partner performing extra-marital acts with a sexual component.

(i) A trait-neuroticism scale, the *Delfse Vragenlijst (DV)* (Appels, 1975), as a measure of obtaining a general description of each sample in terms of neuroticism.

(j) The *Marlowe-Crowne Social Desirability (MC-SD)* scale (Crowne & Marlowe, 1964). Both of its sub-scales (Assert-good and Deny-bad), in a version adapted for use in the Netherlands by van Rooijen & Smoor-van Son (1978), were used. Higher scores on these scales indicate the greater tendency of subjects to attribute to themselves desirable but highly unlikely characteristics, and to deny about themselves undesirable but highly likely behaviour.

Data in support of reliability and validity of the MMQ have been reported by Arrindell *et al*, (1983a,b) and Arrindell & Schaap (1985). Construction of scales (b)-(h) is based on work by Buunk & Bosman (1980) and Buunk & Nijsskens (1980), who also report data supporting scale reliability and validity, examples of items captured by these scales are given in Arrindell *et al*, (1983b). Data pointing to the utility, reliability, and validity of the remaining scales (a, i and j) are given in the cited studies. The scales were randomly distributed within each questionnaire set, the only constraint being that the personality measures (i and j) were preceded by the remaining scales (a to h).

Statistical analyses

Data were compared by means of *t*-tests. Although it is widely believed that such parametric statistics should not be used with data which are not normally distributed, such tests are in fact robust in the face of departures from normality, and may actually be preferred to non-parametric statistics (Everitt, 1979).

In making between-group comparisons, *a priori* contrast tests were utilised. The following contrasts were considered: female agoraphobic patients versus (a) female non-phobic psychiatric patients; (b) maritally distressed female subjects; and (c) maritally non-distressed females. Similarly, these three contrasts were conducted involving the spouses of the above subjects. Thus, these comparisons were made for males and females separately on a relatively large number of variables (14), thereby increasing the risk of obtaining positive results on the basis of chance alone. To counteract this risk, the Bonferroni inequality (Grove & Andreasen, 1982) was employed. This involves choosing an

¹ A high score for a variable indicates a high degree of that behaviour

overall α (0.20 in this study—that is, a relatively large risk of Type I error—in order to find relationships which could be investigated further) and dividing this by the number of tests (k) to be conducted, to result in an individual level of significance (α_i) for each test. In cases where the data fell into small sub-sets, each of which could be used to study a separate group of hypotheses, the Bonferroni inequality was applied separately to each group.

Similarly, in carrying out within-couple comparisons across groups, the Bonferroni inequality was used in an

analogous fashion. These comparisons were conducted by means of multivariate analysis of variance with a mixed three-factor (Couple $\times$ Sex $\times$ Group) design (Hull & Nie, 1981)

The following subsets of variables were considered.

- (1) the MMQ Marital and Sexual Maladjustment scales, the General Marital and Sexual Dissatisfaction scales, and all four communication scales ($k=8$); and
- (2) the MMQ General Life Maladjustment scale, scales referring to the need for interpersonal stimulation, for

* $P \leq 0.025$ (Variable set 1) or $P \leq 0.033$ (Variable set 2), ** $P \leq 0.01$; *** $P \leq 0.001$ (one-tailed tests for comparisons involving female patients versus female controls; two-tailed tests for those involving husbands of patients versus husband controls, unless otherwise specified).

intimacy, emotional dependency, exclusive partner-centredness, and intentional extra-marital involvement ($k=6$).

In the case of unplanned comparisons, *a posteriori* contrast tests (two-tailed, $\alpha=0.05$) were performed, the overall F being significant at $P \leq 0.05$.

Results

Employing overall χ^2 or F -tests ($k=6$, $\alpha=0.033$), comparisons between agoraphobics and their female control counterparts, and between partners of agoraphobics and male controls, on the demographic variables mentioned earlier showed systematic between-group differences on education and occupation only ($P \leq 0.01$).

In view of the relatively small size of the non-phobic psychiatric and maritally-distressed samples, the associations of education, occupation (including employment status), religiosity, age at the time of marriage, and child density (the latter two variables were derived from the demographic variables given earlier) with the criterion measures were carefully examined. Employing the Bonferroni inequality, none of these variables were found to be significantly associated with the criterion variables. Analyses were conducted for the separate sexes, and the above conclusions held for both (observed P s > 0.05).

Corroborating previous findings (Arrindell *et al.*, 1983a,b), none of the criterion measures were found to be meaningfully associated with the sub-scales of the MC-SD scale. In addition, no systematic between-group differences were noted in the subjects' tendency towards socially-desirable responding for comparisons involving the separate sexes across groups (see Table I for means); nor were meaningful differences found in the degree of associations which were denoted by the correlations of the MC-SD sub-scales with the criterion variables across samples by sex.

In line with findings from previous studies (Buglass *et al.*, 1977, Arrindell & Emmelkamp, 1985), partners of female agoraphobics were not found to be more neurotic than male controls. On neuroticism, the partners scored as high as partners of other patients and as high as maritally non-distressed males ($P < 0.0001$), who as a group had the highest mean score (Table I). Female agoraphobics were significantly more neurotic than females from both non-distressed ($P < 0.0001$) and distressed ($P = 0.05$) couple groups, and equally as neurotic as their non-phobic psychiatric counterparts (all tests one-tailed).

In the light of the generally moderate correlations between spouses' scores on the different sub-scales used here, the individuals' scores, rather than the couples' joint score, was used (see also Snyder *et al.*, 1981).

Table II sets out the means and standard deviations for each scale for both husbands and wives for each of the samples. Table III gives the results of *t*-test comparisons; indices of effect size (Cohen, 1977) as a means of evaluating the degree of psychological relevancy of the obtained differences are also given.

Agoraphobic patients versus controls

For the second set of variables ($\alpha=0.033$), it was found that agoraphobics as a group could not be distinguished from other patients, although occasionally they differed from either maritally distressed or maritally non-distressed females. However, except for General Life maladjustment, the means of the three control groups overlapped for each variable of this set. On the General Life scale, maritally non-distressed wives scored significantly lower ($P < 0.01$) than each of the other three groups. For the first set ($\alpha=0.025$), the following results were found.

Marital maladjustment and marital dissatisfaction. Agoraphobics as a group rated their marriages as significantly more maladjusted than did non-distressed females, but significantly less maladjusted than did either maritally-distressed or non-phobic psychiatric females. Non-phobic psychiatric subjects rated theirs as being as maladjusted as maritally-distressed females did; that is, the *a posteriori* Newman-Keuls procedure showed that the groups of non-phobic psychiatric and maritally-distressed subjects formed a homogeneous sub-set (i.e. a sub-set of one or more groups, whose highest and lowest means do not differ by more than the shortest significant range for a sub-set of that size).

Agoraphobics experienced their marriages as being as positively reinforcing as maritally non-distressed subjects did, while females from both the maritally-distressed and non-phobic psychiatric couples group described their marriages as more unpleasant than did the agoraphobic patients. Non-phobic psychiatric females reported their marriages as being as unpleasant as maritally distressed females indicated theirs to be (Newman-Keuls test).

Sexual maladjustment and sexual dissatisfaction. Agoraphobics were found to rate their sexual relationships with their marital partners as less adjusted than maritally non-distressed females did, but as significantly more adjusted than those of female non-phobic psychiatric subjects, and as 'adjusted' as the sexual relationships of maritally distressed female psychiatric subjects. The latter two groups had similar mean scores. Furthermore, agoraphobics described their sexual relationships with their partners as being as satisfying as happily-married females described theirs; non-phobic psychiatric and maritally-distressed females rated their sexual relationships with their spouses as significantly more unpleasant than did female agoraphobics with the former two groups forming a homogeneous sub-set.

Communication. Despite significantly greater self-reported intensities of intimate communication by females from the happily-married couples group, as compared with agoraphobic patients, the latter scored significantly higher than maritally distressed females, and as high as non-phobic psychiatric females. Compared with maritally non-distressed females, the marriages of agoraphobics cannot be characterised by greater patterns of destructive communication. Such patterns are more typical of disturbed marriages, as

reported by the female spouses, than of marriages of female agoraphobics. Furthermore, agoraphobics were found to be comparable to their non-phobic psychiatric counterparts in this respect.

Patterns of 'discongruence in communication, as expressed by the spouses, are not significantly more present in the marriages of agoraphobics than in those of either happily married or maritally distressed wives. In fact, agoraphobics reported the presence of such communication patterns in their marriages significantly less often than did non-phobic psychiatric females. The Newman-Keuls procedure further indicated that non-phobic psychiatric subjects differed markedly (Cohen's $d > 1$) from maritally non-distressed wives in this respect.

Agoraphobics reported avoiding communication with their partners significantly more often than did maritally non-distressed wives, although they did not avoid doing so more often than either maritally distressed or non-phobic psychiatric females. The groups contained by the two homogeneous sub-sets which emerged indicated that the difference between happily married and non-phobic psychiatric groups was largest; agoraphobics as a group lay closer to the happily-married females ($d = 0.50$) than did the non-phobic psychiatric group of females ($d = 1.52$).

Partners of agoraphobic patients versus controls

Systematic (overall) between-group differences were observed on all variables, except on those referring to the Need for Interpersonal Stimulation, the Need for Intimacy, Emotional Dependency, and Exclusive Partner-Centredness. All subsequently conducted t -tests were examined two-sidedly, except those involving the variable Extra-Marital Involvement, which were studied one-sidedly.

For variable set 2 ($\alpha = 0.033$), partners of agoraphobics could not be distinguished from those of non-phobic psychiatric patients on Intentional Extra-Marital Involvement or General Life Maladjustment. Despite differences between the partners of agoraphobics and maritally non-distressed males on these variables, the overlap between the latter group and maritally distressed males rendered interpretation of the results somewhat ambiguous. For variable set 1 ($\alpha = 0.025$), the results were as follows.

Marital maladjustment and marital dissatisfaction. Despite the higher scores of husbands of agoraphobics, compared with maritally non-distressed husbands, the former scored significantly lower than maritally-distressed husbands and as high as partners of non-phobic psychiatric patients on marital maladjustment. In terms of the positively reinforcing qualities of the marriage, no differences emerged in comparisons involving the husbands of agoraphobic patients on the one hand and any of the remaining groups on the other. The Newman-Keuls procedure, however, revealed a sizeable difference ($d > 0.80$) between husbands of non-phobic psychiatric patients and those of happily-married females in terms of marital dissatisfaction (the former group scoring significantly higher), and also similar mean scores on marital dissatisfaction for spouses of non-

phobic psychiatric patients and of maritally-distressed females.

Sexual maladjustment and sexual dissatisfaction. While rating their sexual relationships with their marital partners as being as adjusted and as positively reinforcing as happily married husbands did, the partners of agoraphobic patients scored significantly lower than husbands of both maritally distressed and of non-phobic psychiatric subjects. In fact, the Newman-Keuls procedure indicated that two homogeneous sub-sets could be distinguished, the first comprising happily married husbands and partners of agoraphobic patients and the second comprising husbands of maritally distressed and of non-phobic psychiatric subjects.

Communication. The partners of agoraphobics scored significantly lower on intimate communication than the maritally non-distressed males did, but as a group, they scored significantly higher than the group of maritally distressed males and as high as the group of partners of non-phobic psychiatric patients. Again, the latter two groups could not be distinguished from each other on this variable (Newman-Keuls test).

Patterns of destructive communication are not more characteristic of the marriages of partners of agoraphobics than they are of those of maritally non-distressed male subjects. As compared with the reports of partners of agoraphobic patients, such pathological patterns of communication are more clearly present in the marriages of husbands of both maritally distressed wives and of non-phobic psychiatric patients, with the latter group having the highest mean score. Two homogeneous sub-sets were produced: happily married males and partners of agoraphobic patients; and maritally distressed males and partners of non-phobic psychiatric patients.

The partners of agoraphobics scored as high on discongruence of communication as maritally non-distressed husbands did, but also as high as maritally distressed males. By contrast, the former subjects rated discongruence, as expressed by their agoraphobic partners, as being significantly less present in their marriages than did the husbands of non-phobic psychiatric patients.

Compared with maritally non-distressed husbands, partners of agoraphobics had significantly higher mean scores on avoidance of communication, but significantly lower ones than maritally distressed husbands, and equally high mean scores as partners of non-phobic psychiatric patients. The Newman-Keuls procedure indicated the presence of three homogeneous sub-sets: maritally non-distressed husbands; partners of agoraphobics, and partners of non-phobic psychiatric patients and of maritally distressed females. Hence, the latter groups were very similar to each other on these terms.

Within-couple analyses

No significant sex-by-group interaction effects were noted for the sets of variables used in this study (observed $P_s > 0.20$), so that further inspection of differences within

couples by group was not warranted. Since no significant main effects of sex were noted on sub-scales relating to marital and sexual maladjustment and dissatisfaction, it could be concluded that, in each of the groups of couples, spouses were very much like each other in terms of their ratings on these measures.

Discussion

At odds with the views of Webster (1953), Fry (1962), Goldstein (1973), Melville (1977), Holmes (1982) and others, the present findings indicate that female agoraphobics as a group do not: (a) report their marriages as more maladjusted or unpleasant; (b) indicate greater needs for interpersonal contacts and intimacy outside their marriages; (c) appear to be emotionally more dependent on their partners; (d) show greater tendencies towards centredness on their marital partners; or (e) express greater presence of disturbed patterns of communication in their marriages than their non-phobic psychiatric counterparts. Furthermore, at variance with clinical observations by Fry (1962), the partners of agoraphobics as a group do not show evidence of greater degrees of felt distress as a result of their ideated perceptions of the patients having probable intents of performing sexual acts outside their marital relationships than do the partners of non-phobic psychiatric patients. It could be concluded that agoraphobics and their partners were similar to each other in terms of their ratings on marital and sexual adjustment and satisfaction; the same picture emerged for members of the remaining groups of couples.

When compared with non-phobic psychiatric subjects and their partners, there were no special dimensions which characterised the marriages of the agoraphobic patients or their partners in a more disturbed way. On the contrary, both non-phobic psychiatric patients and their spouses were found to score even higher than agoraphobics and their partners on certain measures. On a number of measures (Marital and Sexual satisfaction), no distinctions could be made between agoraphobics (or their partners) and spouses from the maritally non-distressed couples group. By contrast, on certain measures (Marital and Sexual dissatisfaction), no distinctions could be made between non-phobic psychiatric patients (or their partners) and their maritally distressed counterparts, whereas on the same measures, such distinction could clearly be made in comparisons involving maritally distressed husbands and wives on the one hand and agoraphobics and their partners on the other.

The present findings indicate that agoraphobics and their spouses tend to be comparable to happily-

married subjects in terms of some intimacy aspects (marital and sexual adjustment and satisfaction, and certain communication dimensions), while non-phobic psychiatric patients and their partners are comparable to maritally distressed subjects (e.g. compare the indices of Effect Size (Table III), which were generally of moderate to large magnitude).

Thus, in keeping with previous findings by Buglass *et al.* (1977), not one of the initial hypotheses was supported by the present study. While underscoring the need to incorporate non-phobic psychiatric subjects as controls in the study of marital factors in phobic individuals, the present findings also, in conjunction with those of Buglass *et al.* (1977), Cobb *et al.* (1984), and Arrindell & Emmelkamp (1985) on the psychological profile of the spouse of the agoraphobic patient, underline Symonds' (1973) view that it is necessary to analyse the patient's psychological make-up rather than the marriage or the husband, "since the problem lies not in the marriage, nor in the husband, but within the patient herself." This is not to say that there may not be individual cases in which marital problems serve to complicate agoraphobic suffering, but although important in clinical practice, such individual observations cannot be used as a basis for making general statements concerning the quality of the marital relationships of agoraphobics as a group.

Reviews of psychosomatic illness and family function have suggested that marital pathology may play a role in the selection and perpetuation of symptoms (e.g. Waring, 1977). Research evaluating the marriages of patients who suffer from hypochondriasis, chronic pain, obesity, and myocardial infarction demonstrates marital maladjustment, sexual dysfunction, and emotional illness in the spouse (Waring, 1983). While our results support comparable marital factors in both non-phobic psychiatric patients (marital maladjustment, marital dissatisfaction, and sexual dissatisfaction) and their partners (marital and sexual maladjustment and dissatisfaction, lack of intimate communication, destructive communication, and avoidance of communication), no such support could be found in agoraphobics or their partners. This lack of support in agoraphobia, found here and in the Buglass *et al.* (1977) study, may lie in the fact that on the whole, clinicians have relied on a strikingly conservative working method (the unstandardised one-to-one therapeutic or diagnostic interview), compounded by a concentration on fairly narrow (biased) segments of the population of agoraphobics. In Hafner's (1982) view, "the great majority of agoraphobic patients discussed by therapists in clinical and anecdotal studies have entered and persevered with

some form of psychotherapy, often as private patients, and may therefore be unrepresentative with regard to personality and socioeconomic factors." In this area, sample representativeness with respect to crucial variables is often puzzling.

A problem related to most of the studies pointing to a marital factor in agoraphobia is that the subjects comprising the samples described were chosen and treated by the authors themselves. The experimenter as therapist is a serious methodological problem in marital treatment research (O'Leary & Turkewitz, 1978); the emotional investment and enthusiasm of the author/therapist may not only increase placebo effects and spuriously inflate the success of treatment under evaluation, but may also lead to selective sampling and description of patients. Unfortunately, such selective procedures may lead to serious prejudices and myths about human behaviour that may be difficult to erase (Adelson & Doehrmann, 1980; Hare-Mustin, 1983).

The similarity found here between spouses—particularly those in the maritally distressed and

happily married couple groups—in terms of their ratings on marital adjustment and satisfaction, supports the internal validity of the present study. Marital satisfaction studies tend to demonstrate serious discrepancies between the husband's and the wife's description of the same relationship (Waring, 1982).

It should be borne in mind that only female agoraphobics participated in the present study. It would thus seem advisable to examine this issue employing female partners of male agoraphobics as subjects, since the findings do not necessarily apply to such a group. Nor would they apply to agoraphobics in same-sex relationships.

Prevalence of Schizophrenia in an Urban Population

H. FREEMAN and M. ALPERT

The treated one-year prevalence and point-prevalence of schizophrenia, schizoaffective psychosis, and paranoid state in the city of Salford were derived from the Salford Psychiatric Case Register. The high rates found are attributed primarily to the effects of selective migration from the area. A breakdown of the use of health services in the area by patients with these diagnoses is given; hospital care was found to be the major form of treatment.

Scientific investigation of schizophrenia, as of other forms of major psychiatric disorder, has been much concerned with its epidemiology, yet great uncertainty remains about this aspect of the condition. Variations in diagnostic practices have been responsible for much of the lack of agreement on rates of morbidity, although the introduction of instruments of assessment and diagnosis which can reliably be used cross-nationally, such as the Present State Examination (PSE) (Wing *et al*, 1974) has achieved much more consistency. Other problems, however, have resulted from the use of non-standard populations, e.g. the inclusion of those aged under 15, who are not significantly at risk, or from confusion between point-prevalence and that calculated for varying periods.

The legitimacy of comparing rates from societies at different stages of industrial development has also been questioned. For instance, in poorly developed countries, those affected by psychosis may die more quickly than elsewhere, thus appearing to reduce the rate, or there may be more organic psychoses, which are confused with schizophrenia (Leff, 1981). Both Torrey (1980) and Warner (1985) claim to have elicited striking differences in the data on prevalence of schizophrenia between highly industrialised and other countries, with much lower rates in the latter, so that 'civilisation' is then identified as an important aetiological factor. However, the WHO cross-national study of incidence (Sartorius *et al*, 1986) confirms the previous consensus view that the rates at which new cases appear in any population are very similar world-wide; what happens subsequently to these cases, though, would be expected to vary – at least to some extent – with cultural, economic, and other local conditions. Finally, the effects of migration are often complex (Giggs, 1985), but might perhaps account for substantial differences between areas in their prevalence of schizophrenia.

In industrialised countries, prevalence rates are especially important due to their implications for the

provision of services, since schizophrenia makes long and heavy demands on these, being a mainly chronic disorder of intermittent and variable duration. Hence, rates need to be calculated for geographically defined populations, which has the advantage of ordering the data along a single axis, regardless of other characteristics of the study design (Jablensky, 1986). Although 'true' prevalence could only be determined by examining every member of a defined population with a standard diagnostic instrument (and then only for one point in time), 'treated' prevalence might give a reasonable approximation to it in certain situations. The value of a treated prevalence figure should be enhanced if special attention has been paid in that place to record keeping, and particularly if data have been consistently collected for some years from service facilities, with a view to providing material for research; that was the case in the study reported here.

Background

The historical and social background relevant to this study has already been reported (Freeman, 1984). Salford, in the north-west of England, was essentially a small market town until the arrival of industrialisation in the late eighteenth century. It then experienced an astonishing growth of population, mainly from migration, but with both birth and death rates at high levels, for the rest of the nineteenth century. With an area of less than eight square miles, its population continued to rise to a peak of almost a quarter of a million, in the late 1920s; since then, the figure has fallen steadily to under 100 000 in 1981, and continues to fall. This reduction has also resulted mainly from migration (both voluntary and enforced through redevelopment). Birth and death rates have been much lower in recent years than in the earlier part of this century. The migration has been of a differential nature, consisting mainly of complete families and leaving behind relatively more of the old, of single-parent families, of one-person households, and of the physically or mentally disabled. In terms of socio-economic status, the population is overwhelmingly working class, and since the greatest part of the housing stock is owned by the

City Council, their administrative policies can be very influential on the kinds of people who occupy different homes. For instance, since high-rise flats are hard to let, they may be made available to previously long-stay patients who are being discharged from hospital.

The Psychiatric Case Register for Salford was established in 1968, with the financial support of the Department of Health & Social Security (Fryers *et al.*, 1970; Wooff *et al.*, 1983); it has been particularly useful as a database, from which studies such as the present one can be derived. In 1974, the Salford County Borough (CB) was approximately doubled in size, to form a new Metropolitan District, but data which referred to the former city area could still be identified separately, and these have been used in the study reported here.

Method

The treated one-year prevalence of schizophrenia was derived from the following population, as provided by the Salford Psychiatric Case Register:

- (a) all persons with a home address in Salford CB in contact with the mental health services on 31 December 1973 (point-prevalence)
- (b) all such persons who came into contact with these services during 1974.

Since 1 January 1968, the Salford Case Register has collected psychiatric and social service data on all persons with a home address in Salford treated by any of the mental health agencies, but excluding treatment from general practitioners (GPs). To establish the number of people with identifiable schizophrenic illness, the Syndrome Check List (SCL) was utilised (Wing *et al.*, 1974). This involved reviewing psychiatric case histories for all patients within the population base who had certain specified clinical diagnoses, as recorded on the Register for 1974. The symptomatology obtained from each case history was rated, coded according to the SCL criteria, and then processed using the CATEGO computer program. Since this was an analysis of patients who had become ill over many years, and since the majority were on maintenance medication, it would not have been feasible to use the PSE on the whole sample at that time. Frank psychotic symptoms would be expected in only a minority of patients (Cheadle *et al.*, 1978); also, since the study was carried out retrospectively, it would not in any case have been possible to obtain PSE data for all patients for 1974. However, PSE data deriving from an earlier investigation were available for some of the patients in the study group, and relevant information from this source was incorporated into the study.

Base data

Statistical data on patients in contact with the services at 31.12.73 were provided by the Register's annual listing of point-prevalence for 1973 ('Census 1973'). This embraces the following categories of contact with the psychiatric services:

- (a) long-stay hospital in-patients: one year or more of continuous stay (including transfers between hospitals, within the same episode of treatment)
- (b) medium and short-stay hospital in-patients: 1-364 days' continuous stay
- (c) day hospital and other day centre patients (currently registered at 31.12.73 and actually attending)
- (d) out-patients with attendances both before and after the census point, with not more than three months between attendances
- (e) patients receiving domiciliary visits from psychiatrists, or visits in general hospital wards on 31.12.73, or both, before and after that date, with not more than three months between visits
- (f) patients currently in contact with social workers at 31.12.73 and defined as having mental health problems, according to the Register criteria
- (g) patients on the books of community psychiatric nurses (CPNs) at 31.12.73.

A second annual listing ('New Episodes 1974') provided equivalent data for psychiatric patients other than those already included in Census 1973 who came into contact with the services during 1974. The New Episodes listing included both patients making a 'first ever' contact with the psychiatric services during 1974, and patients who had had previous contact with the services, but who were not eligible for inclusion in Census 1973.

These two listings provided the base for the initial identification of patients to be included in the initial study group.

Diagnostic categories included in the initial study group

The initial aim of the study was to identify patients with the clinical diagnoses of schizophrenia, schizoaffective psychosis, or paranoid state who were in contact with the psychiatric services at 31.12.73 or during 1974, and to check these by a standardised procedure, in an attempt to establish how many of these diagnoses could be regarded as valid. At an early stage, it was decided that some attempt should also be made, using the same standardised technique, to identify the incidence of schizophrenic illness among patients with other diagnoses, recorded on the same two Register listings. It would have been impracticable to have reviewed the case histories of all patients within the Register base population. However, the diagnosis recorded on the Register is that given by the senior clinician in the Salford psychiatric service who is responsible for the patient's initial episode of care, and in practice, these diagnoses were made by a small number of psychiatrists who had worked together for some time and shared similar orientations and training. Since these diagnoses were made for clinical purposes, however, they could not be expected to have the degree of rigour required for a research exercise. The Register has a mechanism for altering diagnosis, if this seems to be necessary when the patient makes a subsequent service contact.

An attempt was therefore made to identify those categories considered most likely to be used in difficult

borderline cases, or when mis-diagnosis occurred, or when patients previously diagnosed as schizophrenic subsequently presented with non-schizophrenic symptoms. Initially, these other diagnostic categories consisted of certain functional psychoses, as well as paranoid and schizoid personality disorders. As the study progressed, however, it became apparent that further groups should be incorporated; the original list was therefore expanded to include all other personality disorders and functional psychoses, and the final list of diagnostic categories covered was: schizophrenia (including schizophrenia, schizoaffective psychosis, paranoid state, and morbid jealousy); mania (including hypomania); severe depression; depressive delusions and/or hallucinations; history of mania and depression, history of mania and depression and/or hallucinations; psychosis, not otherwise specified; personality disorders.

The two Register lists comprised 924 names, a few of which were later found to be ineligible because they did not have a home address in Salford CB during 1974. The final list of the initial study group consisted of 909 patients, of whom 553 were in contact with the psychiatric services at 31.12.73 and the remaining 356 came into contact during 1974. This method makes the assumption that a patient's diagnosis did not change during the study period, however, it should not be taken to mean that every subject was suffering from schizophrenia *throughout* the year.

Expansion of the study group

It became apparent that in any one year, a few known schizophrenics might have been in contact with the psychiatric services but, being free of psychotic symptoms, be given a Register diagnosis (e.g. depression) other than schizophrenia or one of the other diagnostic groups listed above. At that time, the diagnostic hierarchy of the Register was not always strictly observed (although this was corrected shortly afterwards). To ensure that such patients would not be missed, it was decided to include in the study any individuals who had appeared on the Register's annual prevalence listings before 31.12.73 with a diagnosis of schizophrenia, schizoaffective psychosis, or paranoid state, and who were in contact with the defined psychiatric services in 1974, but with a diagnosis for that year which did not fall into any of the groups listed above. It was also decided to include any patients who appeared on the Register's subsequent annual prevalence counts (up to 31.12.79) with a diagnosis of schizophrenia, schizoaffective psychosis, or paranoid state, but who at 31.12.73 or during 1974 were recorded with a diagnosis other than those listed above, the number of these was very small. However, no patient data from later than 31.12.74 were included in the assessment.

At the same time, a comparison of lists of patients receiving depot neuroleptic injections from CPNs in 1973-74 with the Register's annual prevalence listings for 1974 revealed that some patients known to be receiving injections at this time were not included in Census 1973 or New Episodes 1974. The CPN service was then in its early stages in Salford, and Register recording of CNP contacts at that

time was known to be incomplete. In an attempt to identify these and any other eligible patients who may not have been included in the Register's annual prevalence for 1974, listings were made of all patients with diagnoses of schizophrenia, schizoaffective psychosis, or paranoid state from all annual point-prevalence and new episodes lists from 1.1.68 to 31.12.79 (the latest list available at that time). Those patients who appeared on annual prevalence listings both before and after 1974, but not in 1974, were identified; they numbered 134. These procedures also revealed that a further 260 patients with a diagnosis of schizophrenia, schizoaffective psychosis, or paranoid state appeared on Register annual prevalence listings before 31.12.73 but not subsequently, and 149 appeared after 31.12.74 (up to 31.12.79), but not previously. The Register manual record cards for all these patients were therefore examined, to ascertain whether any were, in fact, in contact with the psychiatric services during 1974, and all found to be eligible were incorporated into the study group.

These procedures resulted in the identification of an additional study group of 150 patients; together with the initial study group, this gave a total of 1059. Of the 150, 53 were at this stage known to have been in contact with the mental health services in 1974. For the remaining 97 patients, the following data sources were examined, to establish whether or not they had had contacts in 1974: hospital and social services case notes; information about CPN injections not yet transferred to the Register; and injection record cards at the hospitals.

Those remaining patients who were not positively identified as having contacts with the psychiatric or social services during 1974 could have been receiving maintenance treatment from GPs in 1974; it was decided to retain them within the study, but to identify them separately. Investigation of case notes had already established that some of these patients had in fact received such treatment (initiated by the specialist psychiatric services). Further information was then sought from GPs about the remaining 42 patients; those for whom there was no positive evidence of such treatment were then eliminated from the study.

Coded information on a large number of the patients was then cross-checked with the results of PSE interviews on the same patients, carried out for a previous study (Cheadle *et al.*, 1978). Additional information from the interviews was incorporated into the present study, and in a number of cases confirmed the presence of symptoms for which there was insufficient positive evidence in the case notes, and which were necessary to give a CATEGO classification in one of the schizophrenia groups. The opportunity was also taken to make further checks on the data collection and coding, using any additional information which had come to light; e.g. through enquiries at other hospitals, or from data collected over a number of years on patients treated by depot neuroleptics.

Attempts were made to examine and summarise all available hospital and social service case notes for the 1059 patients in the study group. Notes for 18 patients had been lost or destroyed, but only three of these had a diagnosis of schizophrenia or paranoid state recorded on the Register, and none had had an extensive history of contacts with the psychiatric services.

Results of classification

The following CATEGO classifications (Wing *et al.*, 1974) were regarded as likely indicators of schizophrenic or paranoid illness:

- (a) schizophrenic psychoses: S+, S? (subclasses NS+, NS?, DS+, NSMN/DSMN, NSPD, DS?)
- (b) paranoid psychoses: P+ (subclasses DP+, DPMN, DPPD)
- (c) borderline or doubtful psychoses: O+ (subclasses CS+, CSMN, RSMN, RSPD, CSPD).

For all cases which received one of these classifications, the CATEGO result was compared with the clinical diagnosis, as recorded on the Register. In discrepant cases, where the Register diagnosis was other than schizophrenia or paranoid state, the case note summaries and codings were re-examined, and if necessary the ratings amended and reprocessed. At this stage, all cases ($n=16$) recorded as having organic aetiologies, or where alcohol or drug involvement were considered to be the primary feature of the illness, were excluded from the 'schizophrenia' group.

Where the CATEGO processing resulted in classifications of P? (subclasses DP?, DP?/AP?) or O? (subclasses RS+, RS?, SS, UP+, UP?, XP), the case note summaries were also re-examined, and if possible additional symptom information was sought. Cases which were then still considered as doubtful were not included in the 'schizophrenia' group.

A further investigation of clinical evidence was also carried out for those patients with a Register diagnosis of schizophrenia, schizoaffective psychosis, or paranoid state, but who did not emerge from the computer processing with one of the S, P, or O classifications listed above. Again, if necessary, symptom ratings were revised and reprocessed.

Finally, a group of 588 patients was identified as forming a 'main schizophrenia group' (including paranoid states), and an additional 36 patients formed a 'borderline group'; 538 patients in the main group and 32 in the borderline group had had a Register diagnosis of schizophrenia, schizoaffective psychosis, or paranoid state in 1974. A further 100 patients in the study group had Register diagnoses in the schizophrenia/paranoid groups, but were not confirmed as satisfying our criteria for those categories. Fifty patients in the main group and four in the borderline group did not have a Register diagnosis of schizophrenia, schizoaffective psychosis, or paranoid state relevant to 1974. However, further examination of these patients' records revealed that almost all of them had either at some time other than in 1974 been recorded on the Register as having diagnosis of schizophrenia or paranoid state, or had a clinical diagnosis in these groups which had not been recorded on the Register. They were therefore included.

All case-note assessments were carried out by the same person.

Results

Final allocation of cases to the main and borderline groups.

Analysis by the CATEGO major classes and by Register diagnosis respectively showed a considerable consistency of diagnosis, when the two methods were compared (Table I).

Out of 588 patients in the main group in the study, 50 had received other diagnoses on the Register; 100 patients who had received a diagnosis of schizophrenia, schizoaffective psychosis, paranoid state, or morbid jealousy in the Register did not have that diagnosis confirmed by this study.

The results given below are for the main and borderline groups combined.

Nature of contact with services. For the one-year period, there were a total of 624 subjects, of whom 546 were in contact with specialised psychiatric services, as defined by the Register, 52 were in contact with their GP only, and 26 were in contact with social services only. The point-prevalence numbers for 31.12.73. were 404 for the specialist services and 14 for social services only; no figure could be obtained for GP contact only.

The same figures have been calculated in terms of rates per thousand adult population (aged over 15) and per thousand total population, the addition of the borderline group made a difference of 0.4 per thousand to the rates for total annual period prevalence. Thus, all forms of care account for 6.8 per thousand adult population, over one year.

In-patients The point-prevalence data (31.12.73) showed that patients resident for 24–44 years were the largest subgroup, representing 42% of the in-patients and 15% of the total one-year prevalence. The next largest group had been resident for 10–24 years, representing 24% of all in-patients and 8.5% of all patients. The two groups resident for 1–4 years and 5–9 years each contributed about 10% of the total in-patients, while the groups of under one year and of 45 years or more were each about 7%.

Nine long-stay in-patients died during 1974; eight of these had been in hospital for 15 years or more, and five were aged 75 or over. Thirteen long-stay in-patients were discharged during 1974; all except three were aged 45 or over, and four had been in hospital for at least 35 years. Only one long-stay in-patient was aged under 25, whereas 38.5% were aged 65 and over. In terms of population rates, all in-patients represented 2.45 per thousand of the adult population and 1.86 per thousand of the total population.

The total number of in-patient days for patients with a confirmed diagnosis of schizophrenia was 73 909, compared with 64 106 for all other patients. The average length of stay for the former was 137.4 days, and for the latter 42.6 days.

New cases in 1974. Thirty-five cases had their first contact on the Register in 1974. Of these, 19 were known to have had some previous psychiatric care, nine cases were definitely known not to have had such contact before, and in seven cases this information could not be determined.

Age and sex distribution. The male rate (7.02 per thousand adult population) is somewhat higher than the female

TABLE I
Treated prevalence of schizophrenia in Salford CB, 1974: final allocation of cases to main and borderline groups, analysed by CATEGO major classes and by case register diagnoses

Catego major class	Description	Schizophrenia, Schizoaffective psychosis, paranoid state				All other diagnoses				Total			
		Main group	Borderline group	Excluded	Total	Main group	Borderline group	Excluded	Total	Main group	Borderline group	Excluded	Total

TABLE II
Age and sex of patients (main and borderline groups) for annual prevalence, 1974

Age group	Age and sex-specific rates ¹ per 1000 population		
	Males	Females	Total
5-24 years	2.17	1.14	1.67
25-44 years	8.33	5.77	7.08
45-64 years	9.50	10.52	10.03
65 years & over	6.47	6.98	6.80
Total annual treated prevalence	7.02	6.61	6.80

¹Including patients with paranoid states

(6.61), but females had a slightly higher rate in the age-group 45 and over. Among age-groups, the highest rate was for those aged 45-64, with almost identical rates in the 25-44 and 65-and-over groups; the rate for those aged 15-24 was very low (Table II).

Comparison with general population. The estimated population, aged 15 and over, of Salford CB in 1974 was 91 700. Those aged 65 and over comprised 18%, almost exactly the same as their proportion in the total one-year period prevalence of schizophrenia, but the age-group 15-24 represented 21.5% of the adult population, compared with only 5.5% of the one-year prevalence. The 24-44 age-group was 28.5% of the general population, which was almost the same as its proportion of the prevalence (29.5%), but the 45-64 age-group was only 32% of the population, compared with 47.5% of the one-year prevalence.

TABLE III
Treated prevalence of schizophrenia¹ in Salford CB. statistics on service usage for 1974

Service usage	Main group only	Main and borderline group
In-patients at 31.12.73		
<i>n</i>	211	225
% of group total	35.9%	36.1%
Other patients admitted in 1974		
<i>n</i>	78	84
% of group total	13.3%	13.5%
Total in-patients		
<i>n</i>	289	309
% of group total	49.1%	49.5%
In-patient admissions (including readmissions)	98	107
Total in-patient days	73 909	78 740
Day patient days	7 500	8 231
Patients with day patient attendances	40	43
Out-patient attendances	484	520
Patients with out-patient attendances	179	192
Domiciliary visits	10	13
Patients receiving domiciliary visits	10	12
Patients receiving out-patient depot injections	171	180
Patients on the books of social workers (mental illness referrals) ²	113	123
Total days on the books of social workers (mental illness referrals) ³	16 174	17 214
Patients who died	12	13
Patients known to have moved from the area	7	7
Patients with GP contact only	50	52
Patients in contact with the psychiatric services	538	572
Total patients	588	624

¹Including paranoid states

²Including 6 with number of days not known

³Excluding those mentioned in note 2

Marital status Single patients represented 54% of the total annual period prevalence, but 69% of the long-stay in-patients, and 72% of those in contact with social services only. The exact rate of unmarried adults in the general population of Salford for 1974 is not known, but is much less than any of these percentages.

Domestic unit. At the time of inclusion in the study, 33.5% of subjects were in hospital, 24.5% with family of marriage or cohabitee, 21.5% with parents, siblings or children, 10% living alone, 6% in hostels, groups homes, or elderly person's homes, and 5.5% not known or in other situations. The percentage of males living with parents (24%) was much greater than that of females (9.5%). Only 14% of males were living with a spouse or cohabitee, compared with 35% of females. Sex differences in the other categories were negligible.

Service usage. Table III summarises the use of different categories of service

Comparison of service usage There were 538 schizophrenic patients in contact with the psychiatric services during 1974, compared with 1503 patients with all other diagnoses. Mean hospital in-patient days per schizophrenic patient (137.4) were more than three times those for all other diagnoses (42.6%), while total in-patient days for schizophrenics (73 909) were substantially more than those for all other diagnoses (64 106). Day-patient days (7500) were about one-third those for all other diagnoses (22 300). Combined out-patient attendances and domiciliary visits (494) were less than one-fifth of the total for all other diagnoses (2754). Schizophrenic patients had 16 174 days on the case-books of social workers, compared with 43 724 for patients with all other diagnoses.

Discussion

The study measured morbidity through service contacts—a method proposed by Odegaard (1946), on the assumption that when a psychiatric service is readily available to a whole population, any member suffering from a severe mental disorder will make contact with the facilities sooner or later. This view was supported by data from the Danish island of Samsø, where the service has been free and accessible over a number of years; referral to the specialist facilities was taken as the criterion of 'caseness' in the epidemiological studies there (Stromgren, 1968; Nielsen, 1976). Jablensky (1986) states that in spite of the well documented presence of unrecognised psychiatric morbidity in the community, the importance of epidemiological investigations of treated (or 'declared') cases has not diminished: "surveys based on service contacts can answer questions about the

pathways leading to treatment and management, about the social and personal consequences of being diagnosed as mentally ill, and also, in areas of sufficient density of treatment facilities, questions about incidence and prevalence. A carefully designed survey of service contacts can be a reasonable approximation of a door-to-door survey". Salford readily satisfies Jablensky's requirement of density of treatment facilities (Freeman, 1975).

The rates of 'declared' schizophrenia found in this survey are high, relative to most published figures. Cooper (1978) summarised the results of 15 investigations from 12 countries, carried out between 1929 and 1972, which gave one-year prevalence rates between 1.5 and 4.2 per thousand total population, but most were in the range 2.0–3.5 per thousand. Jablensky (1986) recorded 19 surveys in Europe based on service contacts (although one dealt only with depressive disorders); his conclusion, from this and other forms of epidemiological enquiry, is that "the most striking finding concerning schizophrenia is the relatively good agreement between the rates of prevalence, incidence and morbidity risk obtained in different surveys". This relative concordance of results is despite much lack of unanimity about the operational definition of schizophrenia.

The association of these relatively high rates with the predominantly working-class population of Salford CB is consistent with previous studies showing an excess of schizophrenia in lower social classes; however, this is unlikely to be an aetiological association, as Kohn (1974) and Warner (1985) have claimed. The data on marital status are also in agreement with previous findings; however, in most industrialised countries there are now significant numbers of couples living in stable unions, although unmarried. No data were available on cohabitations, but the number in this sample is believed to have been very small.

The results of the present study emphasise that large samples of schizophrenics, derived from whole populations, are predominantly middle-aged. This is consistent with the condition being one of relatively low incidence (mainly at a young age), but of high prevalence due to its low mortality and its tendency towards a chronic course.

Very high prevalence rates, similar to those reported here, have also emerged from Ireland: the point-prevalence figure for three mainly rural counties was 8.3 per thousand of the adult population (Walsh *et al*, 1980). In addition to possible effects of differential migration, other suggested influences there were "historic-cultural characteristics such as an over-generous provision of in-patient facilities, a passive-submissive tendency on the part of patients

to accept hospitalisation, a paternalistic attitude and practice on the part of psychiatric personnel, and a lack of involvement of primary health care personnel". Murphy & Vega (1982) reported an excess of first admissions for schizophrenia among Catholic males (both in Northern Ireland and Eire), which declines along the geographical axis from south-west to north-east; the percentage of unmarried males in the western Irish counties is double that in the eastern. There is no reliable evidence, however, of a higher-than-average incidence of schizophrenia in Ireland (Ni Nuallain *et al*, 1984).

Jablensky (1986) states that no clear-cut support has been found for the hypothesis that geographical rates of schizophrenic morbidity are affected by negative selection, through the out-migration of healthier individuals. However, it is noteworthy that County Roscommon showed a 50% fall in population during an earlier period of 50 years (O'Hare & McHugh, 1982), which was the same as that for Salford CB in the 50 years from 1928. One statistical effect of such population decline is that the long-stay in-patient rate will be artificially high, because those patients who have been in hospital for many years derived from a much larger population than the current one. Although people migrate for many reasons, both voluntary and involuntary, it would seem likely that areas which have become economically and culturally demoralised (as both western Ireland and inner city Salford could be regarded as being) will lose relatively more of their healthier people. Those left behind represent what Strömberg has described as a 'residual population', in which many kinds of disability have a high prevalence; the opposite situation is found in suburban areas or new towns.

The results of this survey give totals for the use of all categories of psychiatric care by every person suffering from schizophrenia in the defined population, over a period of one year. The heavy demands made by schizophrenia in the hospital care of psychiatric disorder from this particular population are manifest

in the data. The part played by day care in the treatment of schizophrenia is surprisingly small, considering the value widely placed on this for chronic and recurrent psychiatric disorders. Less than one-twelfth of the total identified cases had no contact with any specialist service during the year (i.e. they received GP care only). The contribution of social services was also relatively modest: about one-fifth of the total were in contact with a social worker during the year, and a small number of patients received day care at a local authority centre. A study of chronic schizophrenic patients living outside hospital in Salford in 1976 (Freeman *et al*, 1979) confirmed this picture, and showed that the extent of social service care for any patient tended to be in the same proportion as care from the hospital-based services. At the time of the present study, therefore, the care of schizophrenia in this population was largely the responsibility of the National Health Service psychiatric facilities. Subsequently, the CPN service has been substantially developed, but this was largely in addition to the pre-existing services (Wooff *et al*, 1983).

By pricing each form of care, it would be possible to calculate the total cost to public funds of this condition for a total population – something which has not been done up to now. Results have also been calculated separately for electoral wards in Salford CB, and these small-area variations will be published elsewhere. On the basis of this study, it seems reasonable to propose that predominantly working-class industrial communities that have suffered considerable population loss will show prevalence rates of schizophrenia that are substantially higher than accepted averages for developed countries.

Acknowledgements

This study was funded by the Department of Health and Social Security. The Salford Psychiatric Case Register is funded by Salford Health Authority, the Department of Health & Social Security, and Salford Social Services Department. We would like to thank Lyn Miller, Professor Erik Strömberg, and Professor John Cooper.

HLA Antigens in Schizophrenia: A Family Study

R. CHADDA, P. KULHARA, T. SINGH AND S. SEHGAL

HLA haplotypes A and B were studied in eight families with two or more schizophrenic members. All index cases and all but two sick relatives satisfied Research Diagnostic Criteria for the diagnosis of schizophrenia; 45 subjects were studied. Data were analysed by sequential tests for the detection of linkage and by the affected sib-pair method. The results do not support a linkage between HLA and schizophrenia.

There is considerable evidence that genetic factors contribute significantly to the aetiology of schizophrenia. Though various putative modes of transmission, ranging from Mendelian dominant/recessive inheritance to polygenic inheritance, have been suggested, the exact mode of transmission remains an enigma (Slater & Cowie, 1971; Gottesman & Shields, 1982).

The possibility of locating a genetic marker in schizophrenia offers an opportunity of opening up the entire field of genetic research to further scientific enquiry. A genetic marker is an inherited characteristic which is polymorphic in nature, has a known mode of transmission, and can be assigned or potentially assigned, a precise chromosomal location. It should be specific, readily detectable, and unaffected by the state of illness or recovery (Watt, 1982; McGuffin *et al*, 1983). A trait is 'polymorphic' when it exists in two or more forms, with each genetic variant existing at a frequency of 1% or more in the general population.

Recently, human leucocyte antigens (HLA) have been demonstrated to be associated with various disorders, mostly of a chronic nature – e.g. ankylosing spondylitis, juvenile diabetes, and multiple sclerosis (Svejgaard *et al*, 1975; Thomson, 1981) – all of which have an uncertain aetiology and pathogenesis. Since there are certain similarities in this respect between these disorders and schizophrenia, HLA has been studied in relation to that condition.

Two approaches have been used: in some studies, the incidence of various HLA antigens in the general population has been compared with that in schizophrenic patients (Cazzullo *et al*, 1974; Smeraldi *et al*, 1976; Crowe *et al*, 1979; Miyanaga *et al*, 1984). The results are diverse and conflicting, but there appears to be greater agreement when the disorder is divided into sub-types (McGuffin *et al*, 1981; Ivanyi *et al*, 1983). The other approach, utilising a pedigree paradigm, has attempted to demonstrate linkage

between HLA and schizophrenia (Turner, 1979; McGuffin *et al*, 1983). Here again, the results are conflicting, with Turner (1979) finding evidence for, and McGuffin *et al* (1983) against linkage.

The present study was undertaken with the aim of exploring the relationship between HLA and schizophrenia.

Method

Selection of families

To select suitable families, case records of patients diagnosed between January 1980 and December 1983 as schizophrenic were scrutinised, and those patients who had a positive family history of schizophrenia in one or more living parents or siblings were identified. In addition, colleagues were requested to refer any such patients.

Families were selected for linkage analysis if they contained at least one living parent and two offspring. To study only familial psychosis and avoid inclusion of 'sporadic' forms of the disorder, attempts were made to select large families with two or more schizophrenic members. Eight families were thus identified and found suitable for the study. Many other families, though suitable for linkage analysis, were not included because they were not approachable, or because not enough consenting members were available.

Diagnosis

Probands and all the available relatives were interviewed. All index cases satisfied Research Diagnostic Criteria (RDC) for the diagnosis of definite schizophrenia (Spitzer *et al*, 1978). Relatives who fulfilled RDC for definite schizophrenia or matched the description of schizophrenia spectrum disorder of Kety *et al* (1968) were designated as 'sick', while all others were considered to be psychiatrically healthy for the purpose of the investigation.

Of the available total of 64 subjects in the various families, HLA typing was carried out in 45; of these, 16 were classified as RDC schizophrenia and two as schizophrenia spectrum disorder.

HLA typing

All subjects were called to the Department of Immunopathology, and HLA typing A and B was carried out on the same day, using fresh venous blood. Antigens C and DR were not typed, due to lack of facilities. A standard method of micro-lymphotoxicity test, described by Terasaki *et al* (1974), was employed.

Linkage analysis

Sequential tests for detection of linkage (Morton, 1955). This method consists of determining the probability of an observed pattern of segregation of two characters in a family for a given range of possible recombination fractions (θ), where θ varies from 0 to 0.5. Dividing the probability for a particular value of θ by the probability for a value of 0.5 gives the relative probability or odds ratio at the value of θ . The log of this ratio gives the 'lod' score (log of the odds). Linkage may be tight or loose; tight if the recombination fraction is low, loose if it is high. A value of 0.5 indicates no linkage. The recombination fraction that gives the highest probability or lod score is also the best estimate of the degree of linkage between two loci.

The lod score method, as devised by Morton, is meant to be applied to regular Mendelian phenotypes, whereas for any plausible single gene model of schizophrenia, the notion of incomplete penetrance needs to be invoked. Incomplete penetrance causes a systematic bias against detection of linkage (McGuffin *et al*, 1983).

Affected sib-pair method for detecting HLA-linked genes in disease (Green & Woodrow, 1977). This test requires no assumption about the mode of inheritance of the disorder, and is not affected by errors due to variation in age of onset, as only the individuals already affected with the disease are studied. It can be used only for families in which there are two or more siblings suffering from the illness.

If, in a sibship of two, a particular HLA haplotype is inherited from a parent by both sibs, this is scored as one repeat. Thus, a sibship of two individuals may show 0, 1 or 2 repeats. For sibships of more than two, where an HLA haplotype is inherited by r siblings, the score is $r-1$ repeats. The expected mean score for a sibship of size s , assuming no linkage, is $2s-4+2^{-s+2}$, and the expected variance is $2^{-s+2}(1-2^{-s+1})$ (Green & Woodrow, 1977).

A total score S can be obtained by summing the scores derived from various families. Similarly, the sum of the means and variances gives total expected mean (μ) and total expected variance (σ^2). The test statistic T is defined by

$$T = \frac{(S - \frac{1}{2} - \mu)}{\sigma}$$

Comparison with a standard normal integral table is then made.

Results

The details of all the families studied are shown in Fig. 1. All the family members, whether tested or not, have been in-

cluded, and the HLA haplotypes identified as mentioned. Table I shows the combined lod scores of the families at different recombination fraction values, presuming the mode of transmission in schizophrenia to be autosomal dominant with complete penetrance. Following Morton (1955), the convention is to regard a lod score of 3 or more as firm evidence for, and a score of -2 or less as firm evidence against any linkage. Any score in between can be

TABLE II
Comparison of present work with earlier studies

Study	Recombination fraction (θ)				
	0.05	0.1	0.2	0.3	0.4
Present	-7.151	-4.201	-1.781	-0.598	-0.129
Turner (1979)	1.351	2.350	2.445	1.688	0.649
McGuffin (1983)	-8.088	-4.187	-1.072	-0.084	0.104

considered as equivocal. The total of lod scores at recombination fractions 0.05 and 0.1 are firmly against the probability of any linkage between HLA and schizophrenia (Table I).

The combined lod scores of the present work were compared with the earlier investigations of Turner (1979) and of McGuffin *et al* (1983) (Table II). Our results are most similar to those of McGuffin *et al*.

An analysis of the data by the affected sib-pair method was made. The scores of repeats (S) was 5, the expected mean (μ) 4, and the expected variance (σ^2) was 2. This gave a T value of 0.354, which at d.f. = 3 is not significant. The result does not favour a linkage between HLA and schizophrenia.

Discussion

The present study fails to support the notion of a linkage between HLA and schizophrenia. Our findings are in agreement with McGuffin *et al* (1983), but not with Turner (1979), though the same sequential method of linkage analysis has been carried out on all three data sets.

Analysis of our data by the affected sib-pair method of Green & Woodrow (1977) also does not indicate linkage between HLA and schizophrenia; this is in agreement with McGuffin *et al*. Turner did not use the affected sib-pair method, but his data were subjected to analysis by this method by McGuffin *et al*, and that too did not favour linkage. However, the small number of sibships is a limitation which must be kept in mind when interpreting the results.

In any linkage study in schizophrenia, there are numerous practical and methodological problems. Finding an adequate number of consenting informative families suitable for the purposes of such studies is a major problem. Despite our identifying a large number of potentially suitable families, only eight could be tested. These difficulties have been highlighted by Watt (1982) and by McGuffin *et al*.

A potential source of error in such studies is the uncertainty of diagnosis of schizophrenia. The

present study has employed RDC (Spitzer *et al*, 1978), and in two subjects (both relatives), the diagnosis of schizophrenia spectrum disorder (Kety *et al*, 1968) was entertained. All the index cases were admitted to hospital at some time, and the sick relatives, with two exceptions, were registered at a psychiatric out-patient clinic. Turner (1979) employed the criteria of Feighner *et al* (1972) for the diagnosis of schizophrenia, but relied quite heavily on the spectrum disorder concept of Kety *et al* (1968). McGuffin *et al* (1983) used the CATEGO system (Wing *et al*, 1974) for the diagnosis of schizophrenia and an objective schedule devised by Khouri *et al* (1980) for identifying schizophrenia spectrum disorder. These three studies thus used strict criteria for the diagnosis of schizophrenia, and the concept of schizophrenia spectrum disorder is common to all. Therefore, our failure to demonstrate a linkage between HLA and schizophrenia lends more support to the view that differences in diagnosis alone cannot account for the discrepant results obtained by Turner and by McGuffin *et al*. There is a strong possibility of a genuine absence of linkage between HLA and schizophrenia.

The status of schizophrenia spectrum disorder remains controversial, and it is debatable whether cases diagnosed as such should be included in a linkage study. It has been demonstrated that a number of non-schizophrenic disorders have a tendency to concentrate in the families of patients with schizophrenia (Heston, 1966; Kety *et al*, 1968; Rosenthal *et al*, 1971; Stephens *et al*, 1975). However, Lidz *et al* (1981) have been critical of this concept, and have challenged its validity. Lowing *et al* (1983), in a reanalysis of the original data of Rosenthal *et al* (1971), found a higher occurrence of spectrum disorders in the families of index cases, compared with controls. In view of the evidence supporting the concept of schizophrenia spectrum disorder, we have included subjects falling in this category in our analysis.

Genetic heterogeneity of schizophrenia is a factor which could lead to failure to establish any linkage between the marker studied and the disease. McGuffin *et al* (1983), in an effort to increase the homogeneity of the sample, analysed the data after excluding families with an admixture of diagnosis, but even then were unable to demonstrate linkage. By using strict diagnostic criteria, we have endeavoured to reduce heterogeneity; our findings do not support the existence of two types of schizophrenia—one linked to HLA and the other not.

Finally, it is important in linkage studies that the mode of transmission of the disorder should be known, which is not the case in schizophrenia. However, we have presented the results of our data

analysis presuming the mode of inheritance to be autosomal dominant with total penetrance. In addition, we have used the affected sib-pair method of linkage analysis which, though less powerful than sequential tests, makes assumptions about genetic modes of transmission unnecessary. Our data are being analysed further, using the assumption that the

mode of inheritance is recessive and autosomal dominant with incomplete penetrance.

Our results do not indicate support for linkage between HLA and schizophrenia. Perhaps studies with more homogeneous samples of schizophrenic families and better methods of linkage analysis are needed to unravel the genetics of schizophrenia.

Late Onset Involuntary Movements in Chronic Schizophrenia: Relationship of 'Tardive' Dyskinesia to Intellectual Impairment and Negative Symptoms

J. L. WADDINGTON and H. A. YOUSSEF

Intellectual impairment, negative symptoms, and medication history were assessed in chronic schizophrenic patients with and without abnormal involuntary movements (tardive dyskinesia). Patients with involuntary movements had received neither longer nor more intensive treatment with neuroleptics or anticholinergics. However, the presence or absence of involuntary movements was prominently associated with the presence or absence of intellectual impairment/negative symptoms; these features are characteristic of the defect state/type II syndrome of schizophrenia, in which structural abnormalities of the brain may be over-represented. The role of subtle organic changes in conferring vulnerability to the emergence of such involuntary movements should be re-evaluated.

More than 20 years of research has failed to identify the essential factors which determine whether late-onset involuntary movements (tardive dyskinesia) occur in individuals receiving long-term treatment with neuroleptic drugs. The extensive literature on this topic (Jeste & Wyatt, 1981; Kane & Smith, 1982; Waddington, 1984; Waddington *et al*, 1986) indicates that affected individuals have had neither longer nor more intensive treatment with neuroleptics, but suggests that older age increases the likelihood of developing involuntary movements. Vulnerability to their emergence resides more within the central nervous system of the individual patient, usually diagnosed as schizophrenic, than with the treatment.

It has been proposed that patients with pre-existing forms of organic brain dysfunction may be more likely to develop involuntary movements. However, previous studies on heterogeneous patient groups with varying indices of organicity are inconclusive on this issue (Kane & Smith, 1982). Increasing attention is now being paid to chronic schizophrenic patients who show intellectual impairment and whose clinical picture includes prominent negative symptoms—the 'defect state' or type II syndrome (Crow, 1980). These characteristics are over-represented in the subgroup of schizophrenic patients who show structural abnormalities of the brain on computerised tomography (CT) scan, particularly ventricular dilatation (see Crow, 1982; Andreasen & Olsen, 1982; Seidman, 1983; Waddington *et al*, 1986). The present study specifically investigated associations between the presence of involuntary movements and of intellec-

tual impairment and negative symptoms in chronic schizophrenia, in relation to exposure to neuroleptic and anticholinergic medication.

Method

Our study population comprised 68 long-stay in-patients, aged 30-90 years, who satisfied the criteria of Feighner *et al* (1972) for a diagnosis of schizophrenia and who consented to assessment.

Movement disorder was evaluated using the Abnormal Involuntary Movement Scale (NIMH, 1976); this was followed by neuropsychological assessment of intellectual/cognitive function using an abbreviated form of the Roth-Hopkins test, similar to that described by Qureshi & Hodkinson (1974). The investigator was blind to clinical and medication histories until after this index evaluation.

There is the possibility that objective evaluation of negative symptoms (e.g. poverty of speech and blunting of affect) in relation to involuntary movements will be compromised by the essentially self-revealing nature of such movements. Therefore, they were indexed as follows: muteness was taken as an extreme of poverty of speech, and considered present when verbal production was absent during motor assessment and during attempts at neuropsychological evaluation; in the presence of muteness, no estimate of intellectual function was made. Blunted affect was considered present when review of those periodic case-note reports made prior to the index evaluation, by the consultant in charge of each patient, made specific reference to the presence of this symptom. While these reports appeared thorough, practice in recording blunted affect would undoubtedly vary between the several consultants involved. Thus, both of these estimates of the presence or absence of negative symptoms were conservative, by virtue of their

sensitivity only to the more prominent signs, but had the clear advantage of objectivity

During the subsequent case-note review, demographic details and history of drug treatment were obtained. Doses of neuroleptics were converted to chlorpromazine equivalents according to standard tables (Davis, 1976) and length, average, and current daily dose and total lifetime intake of neuroleptics were determined. Data were expressed as means $\pm$ SEM or as percentage prevalences, and were analysed using Student's *t*-test or the chi-squared test.

Results

As noted in the majority of reports in patients with long-term exposure to neuroleptics (e.g. Owens *et al*, 1982; McCreadie *et al*, 1982; Karson *et al*, 1983), involuntary movements of the limbs and trunk were rare in comparison with those of the orofacial region. Since several recent studies additionally suggest that limb and trunk movements may constitute a pathophysiologically distinct syndrome (Kidger *et al*, 1980; Karson *et al*, 1983), all further references to abnormal involuntary movements (AIM) relate to these hallmark characteristics of the tongue, jaw, lips, and muscles of facial expression.

Out of our population of 68 chronic schizophrenic patients, 28 exhibited at least mild but definite AIM of one or more orofacial areas; in the remaining 40 patients, either no or minimal movements were present. As recommended by Schooler & Kane (1982), movement examination was repeated within one week of the index evaluation in a random group of 12 patients with AIM, particularly to estimate the reliability of assessments made at the 'mild' level of

abnormality. Of these 12 reassessed patients, abnormality was confirmed in 11; the remaining individual showed minimal movements on that occasion, and was included in the group of 40 patients without abnormality. There were no significant sex differences in the prevalence of AIM, which were present in 8 of 22 males (36%) and in 20 of 46 females (43%).

Medication

Patients with AIM were significantly older than those without AIM (Table I). There was a non-significant trend for AIM patients to have a longer duration of illness and to have been older when first given neuroleptics. The two groups had received neuroleptic drugs for indistinguishable periods of time. However, those with AIM had received significantly smaller average daily doses of neuroleptics, and had significantly smaller total lifetime intakes of neuroleptics. The two groups were not distinguished by the presence or absence of current neuroleptic treatment at the index evaluation.

For those individuals not currently receiving treatment, the period that had elapsed since drug withdrawal did not differ between the two groups (without AIM: 4.9 ± 1.3 years; with AIM, 4.5 ± 1.1 years). Patients with AIM were somewhat more likely to have been drug-free for at least one month (72% were drug-free, compared with 46% of those without AIM) and tended to have spent a longer total time drug-free (3.5 ± 0.8 years drug-free, compared with 2.4 ± 0.6 years for those without AIM) since initiation of neuroleptic treatment; these trends approached, but did not attain statistical significance.

TABLE I
General characteristics and medication histories of schizophrenic patients with and without AIM (mean $\pm$ SEM, unless otherwise indicated)

The two groups were not distinguished by any measure of the anticholinergic treatment which almost all patients had received at some stage during neuroleptic therapy, i.e. current dosage and total duration of treatment with anticholinergics (Table I). Comparisons of anticholinergic doses did not help to distinguish the two groups, because of the consistent use of only a small number of drugs over equivalent daily dose ranges (usually benztropine, 2–4 mg).

Intellectual impairment and negative symptoms

Intellectual impairment was assessed in 48 of the patients; of the remainder, 17 were mute and three refused to co-operate with neuropsychological evaluation. Mean scores were significantly lower in the group with AIM, indicating greater intellectual impairment in comparison with those patients without AIM (Table II). Prominent intellectual impairment was defined by a score of less than 50% on neuropsychological assessment, and occurred with significantly greater frequency in patients with AIM. Negative symptoms, defined as above, also occurred more frequently in patients with AIM; for muteness, this excess was statistically significant, while for blunted affect it just fell short ($P < 0.1$) of significance. Table II also shows the number of patients in each group who showed at least one of these three features, while only 35% of patients without AIM showed one or more of these signs, 89% of those with AIM were characterised by these features ($P < 0.001$). This difference could not be accounted for by the slightly but significantly greater average age of the group with AIM. In two age-matched groups, derived by elimination of data from individuals at the extremes of age, this clinical difference was essentially unaltered; 40% of those without AIM (age = 64.2 ± 1.8 years, $n = 35$), compared with 87% of those with AIM (age = 65.6 ± 2.8 years, $n = 24$), showed one

or more of the characteristics of prominent intellectual impairment, muteness, or blunted affect ($P < 0.001$).

Discussion

The prevalence of AIM (41%) in this group of schizophrenic patients was typical. Patients with AIM had a slightly but significantly higher mean age, consistent with the majority of studies. The phenomenon appears to reflect an increased vulnerability with ageing and chronicity, rather than increased exposure to neuroleptics with increasing age (Kane & Smith, 1982; Waddington & Youssef, 1985). In further agreement with the majority of studies (Kane & Smith, 1982), our schizophrenic patients with AIM had received neither longer nor more intensive therapy with neuroleptics. Rather, patients with AIM had received significantly smaller average daily doses and total lifetime intakes of neuroleptics over their period of exposure. This finding is consistent with the report by Smith *et al* (1978) of a similar inverse relationship between involuntary movements and total neuroleptic intake during hospital treatment. It might suggest that patients with AIM were less severely ill than their counterparts, or that the form of their illness was different in some way.

Over the past few years, there have been a number of reports suggesting that a greater extent of drug-free periods during long-term neuroleptic treatment

may in fact be associated with an increased risk of AIM (Kane & Smith, 1982; Branchey & Branchey, 1984). Our patients with AIM tended to have had more discontinuous treatment, but the data were inconclusive. We also found patients with AIM not to be distinguished by greater exposure to anticholinergic medication. The literature as a whole (Kane & Smith, 1982) supports this finding in relation to vulnerability to AIM.

Although we had greater difficulty in distinguishing our two groups of patients in terms of medication history, the presence or absence of certain symptoms was a powerful discriminator of the presence or absence of AIM: intellectual impairment, poverty of speech, and blunted affect. These are prominent features of the defect state or type II syndrome of schizophrenia (Crow, 1980). Even using the present conservative indices, almost 90% of our patients with AIM had one or more of these symptoms, while only about one-third of those without AIM were characterised in this way. The strength of this discrimination ($P < 0.001$) suggests an intimate relationship between features of the defect state and AIM in schizophrenia.

Other studies support this notion. Regarding intellectual impairment, Famuyiwa *et al* (1979) found schizophrenic patients with AIM to be more impaired on a paired-associate learning test; they did not show greater impairment on the Withers & Hinton test of the sensorium, but were some 15 years younger than our own patients. More recently, Wolf *et al* (1983) found no difference in cognitive function between schizophrenic patients with and without AIM respectively, using the indices of Wechsler and of Rey, in patients a decade younger than our own. However, in younger patients, Struve & Wilner (1983) found those with AIM to be more impaired on the Conceptual Level Analogy Test. Regarding negative symptoms, McCreddie *et al* (1982) noted that older schizophrenic patients with AIM more commonly showed flattening of affect, and older schizophrenic patients with these features of intellectual impairment and negative symptoms may show AIM even in the absence of a history of exposure to neuroleptics (Owens & Johnstone, 1980; Owens *et al*, 1982). Thus, neuroleptics might not cause such movements, but rather, might enhance a usually covert, but sometimes overt predisposition towards AIM (Waddington *et al*, 1983, 1986).

This over-representation of intellectual impairment and negative symptoms in our AIM group might be the basis of their reduced exposure to neuroleptics in the present study. A clinical picture in which these features predominate would require less intense treatment with neuroleptics. The case-notes

revealed that the psychiatrists caring for our patients had attempted to reduce neuroleptic dosage to match the extent of positive symptoms, and also to minimise medication of patients with the defect state, where least benefit is likely to be derived (Crow, 1982). This interpretation is supported by the study of Opler *et al* (1984), who found that schizophrenic in-patients with negative symptoms had been less heavily medicated than patients with positive symptoms. Similarly, the trend towards more discontinuous medication in our patients with AIM may be explicable in these terms: case notes indicate that drug-free periods were not a result of non-compliance, but rather a clinical decision that in the absence of positive symptoms, neuroleptic treatment was not warranted. However, patients with AIM were slightly older, and tended to have had a greater duration of illness when neuroleptics were first introduced; this may in itself have contributed to a less enthusiastic approach to neuroleptic treatment.

Involuntary movements and intellectual impairment/negative symptoms may be two separate manifestations of a common pathophysiological process that both underlays deterioration to the defect state and confers vulnerability to the emergence of AIM during long-term neuroleptic treatment. Our point-prevalence study cannot indicate whether AIM and these features of type II schizophrenia tend to arise together, or whether either one might precede the other. This would only become clear from prospective studies in schizophrenia.

Our data indicate that signs of type II schizophrenia are a much better predictor of the presence or absence of AIM than any variable related to medication. Such features of the type II syndrome have been associated with a variable excess of structural abnormalities of the brain by CT scan, particularly ventricular dilatation (Crow, 1982; Andreasen & Olsen, 1982; Seidman, 1983). While CT scan studies in relation to the presence or absence of AIM are not consistent, this may reflect heterogeneous groups which include non-schizophrenic patients with other potential structural or organic changes (Waddington *et al*, 1986). In the light of the present evidence, we suggest that a role for various subtle organic factors in rendering a patient vulnerable to the emergence of AIM should be reconsidered, not just in schizophrenia but also in patients with other diagnoses who are given neuroleptics and in whom AIM are demonstrable.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.¹

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,²⁻⁵ and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil

DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information

Dosage: (Adults) Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension,

hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08; ampoules (PL0012/0117). **References:** 1. When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P., an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal adult dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties; therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £3.73. **Product Licence Numbers:** PL0014/5941, PL0014/0209. © The Boots Company PLC, Nottingham, England. Further information available on request.

The Nithsdale Schizophrenia Survey V. Follow-up of Tardive Dyskinesia at 3½ years

A. D. T. ROBINSON and R. G. McCREADIE

The point-prevalence of tardive dyskinesia in schizophrenics from a discrete geographical area (Nithsdale, in Dumfries and Galloway Region) in 1981, 1982, and 1984 was 31%, 27%, and 30% respectively. This suggests that the prevalence of tardive dyskinesia in a community of schizophrenics has reached a plateau. In 12% of patients there was persistent dyskinesia, i.e. abnormal involuntary movements were present at all three assessments. Persistent dyskinesia was more common in older patients. The severity of tardive dyskinesia fluctuated between assessments in 41% of patients, indicating that it is only a transient feature in some cases.

A previous study of tardive dyskinesia (TD) in all known schizophrenics in Nithsdale, a historically ancient and geographically discrete part of Dumfries and Galloway Region, found a point-prevalence of 31% (McCreadie *et al.*, 1982); an interim review one year later found a prevalence of 27% (Barron & McCreadie, 1983). It was suggested that as a generation of schizophrenics has now been exposed to neuroleptics, which are thought to be the main aetiological factor in TD (*The Lancet*, 1979), the community prevalence might have reached a plateau. To determine whether this may be so, the present study examined Nithsdale schizophrenics 3½ years after the initial census. It also identified and described patients with persistent dyskinesia.

Method

The 1981 census

The original census, carried out in March 1981, identified all known schizophrenics in Nithsdale. Included in the survey were all in-patients, day-patients, and out-patients of Crichton Royal Hospital who on 1 March 1981 had a firm case-record diagnosis of schizophrenia and whose home address was in Nithsdale. In addition, all the general practitioners in the area replied to our questionnaire and identified schizophrenics known to the practice and receiving treatment. The Feighner criteria for schizophrenia (Feighner *et al.*, 1972) were applied to each patient. The census identified 133 schizophrenics, 117 of whom were examined for tardive dyskinesia.

3½-year follow-up

The repeat census was carried out 3½ years later (20 August 1984) in a similar way to the initial survey. It identified 145 schizophrenics, of whom 70% fulfilled the Feighner criteria for definite or probable schizophrenia, and 88 (61%) were

members of the original cohort: 17% were in-patients, 24% day-patients, 39% out-patients or supervised by a community psychiatric nurse (CPN), and 20% were attending only their family doctor.

We examined 130 of the schizophrenics (90%) for evidence of tardive dyskinesia—all the in-patients, all the day-patients except one, all the out-patients except one, all the CPN patients and 57% of the general-practice patients. To assess TD, we used the Abnormal Involuntary Movements Scale (AIMS) (US Department of Health, Education and Welfare, 1976), in which individual areas of the body are examined and then a global assessment is made: this ranges from 0 (no movements) through 1 (minimal), 2 (mild), and 3 (moderate), to 4, 'severe movements'. The assessments exclude tremor, akathisia, and dystonia. Our assessments were made during a 6-week period by two psychiatrists, and 12% of patients were examined independently by both psychiatrists to assess inter-rater reliability.

Of those examined, 16% were not currently receiving neuroleptics, but only 5 patients (4%) had no record of such drugs having been prescribed in the past; 27% were receiving anti-parkinsonian drugs. The length of time for which patients had been receiving neuroleptics since the initial census and the route of drug administration were determined; no attempt was made to estimate the total quantity of medication prescribed, as such information would probably have been inaccurate, especially for out-patients and general-practice patients.

Differences between groups were tested by the chi-squared test.

Results

Inter-rater reliability on the 5-point global AIMS scale was high (Spearman rank correlation coefficient $r = +0.82$, $P < 0.01$).

1984 prevalence of abnormal movements

If patients with a rating of at least 'mild' on the global AIMS

TABLE I
Point prevalence of abnormal involuntary movements among schizophrenics in Nithsdale (1981, 1982, 1984)

Abnormal movements (AIMS score)	1981		1982		1984	
	All patients (N = 117)	Subgroup* (n = 88)	All patients (N = 122)	Subgroup* (n = 88)	All patients (N = 130)	Subgroup* (n = 88)
Mild/moderate/severe	31%	35%	27%	32%	30%	30%
Nil/minimal	69%	65%	73%	68%	70%	70%

*Subgroup: patients rated on all three occasions

scale are considered to have definite TD, then the prevalence is 30% (Table I): 18% with only oro-facial movements, 3% with trunk and/or limb movements, and 9% with both oro-facial and distal movements.

Persistent dyskinesia

Of the 145 patients, 88 (61%) had been examined on all three occasions. The prevalence figures for definite TD in this subgroup in 1981, 1982, and 1984 were 35%, 32%, and 30% respectively (Table I). Almost half (47%) of the subgroup had never shown signs of dyskinesia; 12% had dyskinesia on all three occasions ('persistent dyskinesia'); and 41% had dyskinesia on at least one but not three occasions ('fluctuating dyskinesia'). In the 'fluctuating' group, the severity of dyskinesia increased over time in 11% of cases, decreased in 17%, and showed no trend in 13%. The details of these changes are presented in Table II.

Patients with persistent dyskinesia were compared with those who had never had abnormal movements, on the basis of sex, age, hospitalisation status. Feighner categorisation, and medication (current and previous, antipsychotic and

anti-parkinsonian). There were no statistically significant differences between the two groups, although the trend was: that patients in the persistent dyskinesia group were older (mean age 51 years vs 45 years) and more often in-patient: or day-patients (73% vs 44%).

In the group with fluctuating dyskinesia, when those with worsening TD were compared with patients showing decreasing TD, there were no statistically significant differences in the clinical, social, and demographic characteristics outlined above. In particular, there was no clear relationship between the starting or stopping of anti-psychotic or anti-parkinsonian medication and fluctuation in dyskinesia. However, the trend was that patients with worsening TD were younger (mean age 51 years vs 61 years).

Of those with persistent dyskinesia, 9% had only oro-facial movements and 91% both oro-facial and distal movements.

Discussion

The point-prevalence of TD in all known schizophrenics from a given geographical area, assessed on three separate occasions spread over 3½ years, has remained fairly constant between 27% and 31%. It is probable, therefore, that the community prevalence has indeed reached a plateau, and is not likely to increase further with time. As new patients develop schizophrenia and are given neuroleptics, some will develop dyskinesia. These will be balanced in numbers by others dying or recovering from the illness; in the latter group, medication will probably be stopped. The plateau in the present series of studies contrasts sharply with the reported increase in prevalence during the 1970s. As anti-psychotic medication was widely prescribed at that time, the supposed increase in prevalence probably reflect clinicians' increasing awareness of the condition: the true prevalence may well have been essentially unchanged throughout.

Interpretation of our results is complicated by the finding that although about a third of the patient

TABLE II
Patterns of presence/absence of abnormal involuntary movements in a group of 88 schizophrenics all of whom were assessed in 1981, 1982 and 1984

1981	1982	1984	n (%)
Absent	Absent	Absent	41 (47%)
Absent	Absent	Present	4 (4%)
Absent	Present	Present	6 (7%)

Present	Absent	Absent	10 (11%)
Present	Present	Absent	5 (6%)
Present	Present	Present	11 (12%)
			88

had TD at any given time, only 12% of those patients rated on all three occasions had persistent dyskinesia. This latter figure is probably a more accurate assessment of the severity of the problem: point-prevalence figures include mild and reversible TD, and paint too gloomy a picture. Schizophrenics with persistent dyskinesia tended to be older than those with no TD: age is the only factor consistently found to be associated with TD (Smith *et al.*, 1979; Seeman, 1981; Kane & Smith, 1982; Barnes *et al.*, 1983).

41% of patients examined on all three occasions had TD on one or two, but not all three occasions. There are no doubt several reasons for fluctuating dyskinesia (reviewed by Bergen *et al.*, 1984). Deficiencies in assessment, such as within-rater variability (Bergen *et al.*, 1984), lack of sensitivity of the rating scale (Barnes, 1984), or lack of standard-

isation of rating schedules in relation to time of depot neuroleptic administration (Barnes & Wiles, 1983), may be important. It is unlikely, however, that these methodological problems can entirely explain fluctuating dyskinesia: the present findings therefore emphasise the transient nature of TD in some patients. In the present study, worsening dyskinesia over time was more common in young patients. Such patients had probably had a shorter exposure to neuroleptics, which had not yet produced their maximum effect; as the years go by, dyskinesia may be expected to worsen in them.

Deliberate Self-harm: How Do Patients View Their Treatment?

D. PIERCE

The opinions of patients who had caused deliberate self-harm about the attitudes of doctors, nurses, families and others towards their acts were studied. Their views of the attitudes of hospital staff were found to be markedly different from attitudes reported elsewhere by staff themselves. There were no differences between the patients' views of their handling by nurses, families, and others towards their acts were studied. Their views of the attitudes of families were unsympathetic. A significant association was found between repetition of an act of deliberate self-harm and the perception of an unsympathetic attitude within the family.

While we have information about the attitudes of doctors and nurses (Patel, 1975; Ramon *et al*, 1975) and of people close to the patient (James & Hawton, 1985) towards cases of deliberate self-harm (DSH), there is little about how the patients themselves view the treatment they are given after their acts of self-harm. It is known for instance that hospital staff have a different attitude towards cases of this kind from that towards patients presenting with physical illnesses (Patel, 1975), but we do not know how much of this is apparent to the patients. There is evidence that nursing and medical staff differ significantly between themselves in their feelings of sympathy towards parasuicidal patients (Patel, 1975; Ramon *et al*, 1975); if patients are aware of these differences, there may well be implications for their assessment and management in hospital.

Significant other persons tend on the whole to be sympathetic in their reactions (James & Hawton, 1985), although Morgan (1979) has described expressed hostility and a definite lack of sympathy in some cases. It is of practical importance to know whether such responses are evident to the patients, and if so, whether these perceived attitudes have any effect on their subsequent behaviour. One could argue that a reaction perceived as hostile might discourage a person from repeating his self-harm, while an over-sympathetic response might even promote such repetition. What advice, therefore, should we give to relatives who find themselves in this dilemma?

This study was designed

- (a) to find out how patients view the treatment they have received on general hospital wards after admission for DSH
- (b) to relate these views to the actual attitudes of doctors and nurses towards DSH patients, as previously reported

- (c) to compare the patients' views of the attitudes of professional staff towards them with their views of the attitudes of their families
- (d) to establish whether the patient's view of his treatment by professional staff or by his family is related to the likelihood that he will repeat his DSH.

Method

Patients admitted consecutively to East Glamorgan Hospital for treatment of the effects of DSH were considered for the study, and interviewed as soon as their clinical condition allowed. The interview was a standardised one, used at the hospital for several years, and leads to the measurement of suicidal intent, to a psychiatric evaluation, and to a decision about further management. Patients who were confused or suffering from a psychotic illness were subsequently excluded, as were those unable to provide a significant other person likely to be affected by their action.

At the end of the interview, each patient was asked to give his opinion of the treatment he had received in hospital from the medical and nursing staff in the casualty department and on the ward. He was asked to categorise it as:

- (a) definitely sympathetic and helpful
- (b) neutral, i.e. neither particularly sympathetic or unsympathetic
- (c) definitely unsympathetic and unhelpful.

It was made clear that this opinion was not to be relayed to the staff concerned, and the patient was not asked to complete a form. It was considered that this might be intimidating and thus discourage patients from giving an honest opinion.

He was then asked to provide his opinion of the attitude of his close family or a suitable significant other person to his behaviour, categorised in the same way. If several members of the family were felt to hold varying attitudes, he was asked to report his view either of the overall family attitude or of the attitude of the family member most important to him.

TABLE I
Attitudes of hospital staff: perceived and self-reported

Staff group	Unsympathetic	Attitude: % Neutral	Sympathetic
Senior doctors, self-reported ¹	25	33	42
Patients' view of doctors attitude	12	31	57
Junior doctors, self-reported ¹	44	44	12
Patients' view of nurses' attitude	14	31	55
Nurses, self-reported ¹	40	47	13

1. Figures from Patel (1975)

The patients were followed-up for a year, and a note made of further episodes of DSH leading to hospital treatment. It was not possible to obtain accurate information about episodes treated at home.

The results were analysed using the Spearman rank correlation to measure the degree of agreement between the patient's ratings of doctors, nurses, and families. The Wilcoxon matched pairs test and the Mann-Whitney U test were used to explore the relationships between various subgroups of patients.

Results

One hundred patients were included in the study (37 male, 63 female), and the mean age was 34 years; they were therefore comparable with other reported samples of DSH patients (Birtchnell & Alarcon, 1971; Silver *et al*, 1971). All had been admitted to the hospital via the accident and emergency department, and their mean length of stay in the hospital before interview was a little under 24 hours. All but two were nursed on general medical wards.

Of the total, 55% thought that the nurses had been definitely sympathetic towards them; this was almost exactly the same as the figure of 57% for their view of their treatment by the doctors. Fourteen percent felt that the nurses had handled them unsympathetically, compared with 12% who held the same opinion about the doctors. For the most part, it was the same patients who were unhappy about the attitudes of the different hospital professionals.

The patients' perceptions of the attitudes of both doctors and nurses towards them were markedly different from the attitudes previously reported by hospital staff themselves (Table I).

One-third of the patients believed that their families had been unsympathetic to their action, while 42% felt that they had been helpful; this indicated that the families were regarded as significantly less sympathetic than either nurses or doctors ($P < 0.01$, Wilcoxon matched pairs test). There was no tendency for the same patients to think that both the professionals and their families were unsympathetic. A strong relationship emerged between perceived lack of sympathy on the part of the family and a history of earlier acts of DSH: half of those patients who had harmed themselves previously thought their families unhelpful, and this was

TABLE II
Repetition and perceived attitude of significant other persons

	Perceived attitude: n	
	Unsympathetic	Sympathetic or neutral
Repeaters	8	4
Non-repeaters*	25	63
Total	33	67

* $P < 0.02$ (Fisher's Exact test) for repeaters compared with non-repeaters

significantly different ($P < 0.01$) from the attitude reported by the other patients.

No relationship was found linking the patient's view of his hospital management with the likelihood of repetition, but a connection did emerge between repetition and his view of the family's feeling towards his behaviour. Among those patients who repeated DSH within the follow-up period, as many as two-thirds had regarded their families as unsympathetic after the index episode (Table II). This is a significantly higher proportion than among the non-repeaters ($P < 0.02$). Furthermore, when the 11 patients who had an earlier history of DSH and who considered their families to be unsympathetic were looked at separately, seven of them repeated DSH during follow-up (64%), compared with 6% for other patients ($P < 0.01$). As expected, there was strong tendency for patients with a history of earlier episodes to repeat during follow-up ($P < 0.001$).

Discussion

The substantial differences between the patients' perceptions of nurses' and doctors' attitudes towards them and the attitudes earlier reported by staff themselves suggested that any lack of sympathy felt by staff treating DSH cases is not readily apparent to their patients. If this is so, the finding must be a

welcome one from the ethical point of view, unless one subscribes to the opinion that some degree of unsympathetic handling may discourage repetition. There is a possibility, however, that the apparent differences in perceptions of patients and staff can be explained by a reduction in the antipathy of doctors and nurses towards self-harming patients brought about by improvements in education and training during the years between Patel's study and ours. An alternative explanation could lie in sampling differences between the two studies, but this seems unlikely, as they were carried out in similar settings, involving unselected cases.

It remained true, however, that one in six patients felt that nurses had not been helpful or sympathetic – perhaps not a surprising finding in the light of the percentage of DSH cases reported to have histories of antisocial behaviour (Morgan *et al.*, 1975), who are likely to provoke hostility in all those around them. Yet there was no trend for the same patients to see both families and professional staff as not sympathetic, so that the perceived attitudes may be a true reflection of their handling, rather than simply a mirror of their own personalities.

James & Hawton (1985) have recently shown that 50% of significant other persons express much sympathy after parasuicidal acts, while 3% feel no concern, and 18% show 'little sympathy'. The present study categorised the patients' perceived attitudes of significant others in a different way, but 42% thought that the other person had been definitely sympathetic – a comparable figure to James & Hawton's, suggesting a close correspondence between actual and perceived favourable attitudes of those near to the patient. This is of some interest in view of earlier authors' comments (e.g. Bancroft *et al.*, 1977) on faulty or disturbed communications between DSH patients and those important to them.

The finding that one-third of the patients felt

that their families had been unsympathetic has implications for the management of DSH cases, but this cannot be divorced from the question of the possible effects of this lack of sympathy. The results show clearly that the perception of a lack of sympathy in the family is associated with repetition. If this link is causal, then efforts should be directed to discovering whether this perception is an accurate one and, if it is, to making an attempt to alter it, in the hope of reducing the repetition rate. It seems probable, however, that any negative attitude in the family is itself closely related to a history of earlier DSH episodes. It may therefore be mainly a reaction to a series of acts perhaps seen as manipulative, and the family's attitude might well not have played any causative role in initiating the patient's repetitious self-harming.

For this reason, it will be important to concentrate attention on 'first ever' episodes in elucidating the different forms that family reaction to DSH can take, and in planning experiments to reduce repetition by modifying family responses which are felt to be inappropriate.

From the behavioural standpoint, it would seem reasonable to expect that a patient's belief that those around him were unsympathetic towards him on account of his act would discourage the idea of repetition, but the findings of this study suggest otherwise. It might be fruitful to continue to study the effects of family and staff attitudes on repetition by carrying out experiments which allow some patients to be treated in a more overtly sympathetic way than others.

Moderate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Moderate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Moderate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Moderate 25mg/ml may be transferred directly to the equivalent dose of Moderate concentrate on the basis that 1ml Moderate concentrate is equivalent to 4ml Moderate. **Contra-indications.** Patients with marked cerebral atherosclerosis, pheochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices.** **Moderate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Moderate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 10 x 1.0ml ampoule £48.86. Moderate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.

TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept. Since then worldwide clinical experience has confirmed the efficacy and safety of Moderate in over 800,000 patients.

Moderate is now regarded by many psychiatrists as the standard depot neuroleptic.

MODECATE®

Moderate is available in two strengths, allowing a wide dosage range with convenient injection volumes.

Most patients can be controlled with an injection at intervals of 3 weeks or more. Moderate is less expensive than other depot neuroleptics when comparing equipotent doses.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine,¹ trifluoperazine² and haloperidol³ but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia⁴

DolmatilTM
sulpiride
IN SCHIZOPHRENIA

Prescribing information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 200mg sulpiride. **Indications:** Acute and chronic schizophrenia. **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and early evening) is recommended. **Predominantly positive symptoms:** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily. **Predominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily. **Mixed positive and negative symptoms:** 400mg-600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment. Clinical experience in children under 14 years of age is insufficient to permit specific recommendations. **Contraindications:** Phaeochromocytoma. **Warnings:** Extrapyramidal reactions, principally akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary. After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dosage in a small number of patients in aggressive, agitated or excited phases of the disease process. Dolmatil may aggravate symptoms. Care should be exercised where hypomania is present. Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions:** Epilepsy - anti-convulsant therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney. Pregnancy - the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number:** PL 5299/0006. **Legal category:** POM. **Basic NHS cost:** 63p per day at dose of 600mg daily. **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW3 4DF. **References:** 1. An American Validation Study of the Newcastle Diagnostic Scale

I. Relationship with the Dexamethasone Suppression Test

M. ZIMMERMAN, B. PFOHL, D. STANGL and W. CORYELL

The Newcastle diagnostic index was completed on 159 depressed in-patients, who received the dexamethasone suppression test during their first week in hospital. Patients suffering from endogenous depression had a significantly higher rate of DST non-suppression, were older, were more frequently psychotic, and more frequently lost weight; even after controlling for these variables, DST non-suppression was significantly more frequent in the endogenous group. The relationship between Newcastle scores and the frequency of DST non-suppression was non-linear.

The Newcastle diagnostic scale (Carney *et al*, 1965) has been found to be related to ECT response (Vlissides & Jenner, 1982), response to tricyclic anti-depressant drugs (TCAs) (Rao & Coppen, 1979), and to the dexamethasone suppression test (DST) (Coppen *et al*, 1983; Holden, 1983), yet this scale has received almost no attention in North America. The present report is the first in a series examining its validity, and reports on the relationship between the scale and escape from dexamethasone suppression – a phenomenon which some (but not all) investigators have found to be specific to endogenous depression (Carroll, 1982). Moreover, since two of the ten items on the Newcastle scale (weight loss and nihilistic delusions) may themselves be related to the DST (Asnis *et al*, 1982; Coryell *et al*, 1982; Mendlewicz *et al*, 1982; Targum, 1983; Zimmerman *et al*, 1984), we have examined whether the association between the DST and the scale is due to their mutual association with psychosis or weight loss. Older age may also be associated with both escape from dexamethasone suppression (Nelson *et al*, 1984; Oxenkrug, 1983) and the Newcastle scale (Abou-Saleh & Coppen, 1984), and we therefore, tested whether age is responsible for the significant relationship between the Newcastle scale and the DST.

Method

Throughout a period of one year, the investigators sought the participation of consecutively admitted depressed patients who were at least 18-years old and did not have any of the medical and pharmacological exclusion criteria specified by Carroll *et al*, (1981). In addition, insulin-dependent diabetics (Cameron *et al*, 1984) and patients taking carbamazepine (Privitera *et al*, 1982) were excluded. Only 10% of

the potential participants refused to participate or were mute and unresponsive, and therefore could not give consent.

Faculty members, residents, and medical students obtained psychiatric histories. Two of the authors read these histories, and independently determined whether the patients met the DSM-III (American Psychiatric Association, 1980) criteria for major depressive disorder: those who did not were excluded from the study. This left a sample group of 161 patients. DSM-III criteria were also used to diagnose the patients as psychotic or non-psychotic and bipolar or unipolar; disagreements between rates were resolved by discussion. All diagnoses were made blind to DST results.

Within one week of admission (mean 2.5 days, s.d. 1.6 days), each patient was given 1 mg of dexamethasone at 2300 h; blood was sampled the next day at 0800 and 1600 h. Serum cortisol was measured by radio-immunoassay, using a specific cortisol antiserum obtained from Damon Diagnostics. There was no cross-reactivity with dexamethasone, progesterone, testosterone, or 11-deoxycortisol. The intra-assay and inter-assay coefficients of variation around the cut-off used to classify patients as non-suppressors were 11.1% and 12.2% respectively. Using the same procedure as the depressed patients, 33 normal controls completed the DST. The test's specificity was 97% (one normal was a non-suppressor) with a cut-off of 5 µg/dl, and 91% (three non-suppressors) using a cut-off of 4 µg/dl. Non-suppression, therefore, was defined as a serum cortisol level greater than 5.0 µg/dl at either sampling.

The in-patient psychiatric unit at the University of Iowa is a tertiary care centre, and the majority of patients had received treatment before admission. Unlike many research units, patients are not maintained drug-free for one or two weeks before the DST, but are treated promptly. A previous study from this centre found that medication status was unrelated to DST results (Schlesser *et al*, 1980). In the present sample, only 35 (22.0%) patients received no psychotropic medication during the month prior to admission; 69 (43.4%) patients were taking TCAs; 12

(7.6%) patients were taking monoamine oxidase inhibitors; 23 (14.5%) patients received lithium; 19 (12.0%) patients received other antidepressants such as trazodone or maprotiline; 50 (31.5%) patients took low doses of minor tranquilisers or hypnotics; and 41 (25.8%) patients received neuroleptics. None of the six classes of medication had any effect on DST suppression. For example, 35% of the patients who took a TCA during the month prior to admission were non-suppressors, compared with 36% of those not taking TCAs. Thirteen (37%) of the unmedicated patients were non-suppressors.

Two of the researchers completed the 24-item Hamilton Rating Scale for Depression (HRSD) (Hamilton, 1967), the Beck Depression Inventory (BDI) (Beck *et al.*, 1979), and the Global Assessment Scale (GAS) (Endicott *et al.*, 1976), either on the day the dexamethasone was administered or the day the blood was drawn. These measures were supplemented with questions from the Schedule for Affective Disorders and Schizophrenia (SADS) (Spitzer & Endicott, 1978) on distinct quality of mood, reactivity, and anhedonia. Two patients refused to answer several questions used to score some of the Newcastle items and therefore were excluded from all analyses. The cut-off scores used on the relevant HRSD and SADS items to determine the presence or absence of the Newcastle symptoms are detailed elsewhere (Zimmerman *et al.*, 1985).

A semi-structured life event interview (Zimmerman, 1982), covering the year prior to admission, provided the information to rate the 'no adequate psychogenesis' Newcastle item in 132 (83%) patients. In 91 (57.2%) patients, 'adequacy of premorbid personality' was assessed with a semi-structured interview designed to assess the DSM-III Axis II personality disorders (Pfohl *et al.*, 1984; Stangl *et al.*, 1986). Review of notes and unstructured clinical interactions with the patient were used to rate these two items in the remaining patients.

Data analysis

We used the *t*-test for two group comparisons of continuous variables, a one-way analysis of variance for three group comparisons, and the chi-squared test for comparisons using categorical data. The Mantel-Haenszel procedure was used to examine whether there was a significant association between the DST and the diagnosis of endogenous depression, after controlling for their mutual association with history of weight loss (defined as an HRSD score of 2 on item 16), psychosis or age.

Results

The average age of the 159 patients was 39.6 years (s.d. 16.1 years); 45 patients were male and 114 female. Forty-four (27.7%) of the sample were psychotically depressed. There were 148 unipolar depressives and 11 bipolar depressives. At baseline, the mean 17-item HRSD score was 22.5 (s.d. 6.3), the mean 24-item score was 29.7 (s.d. 8.9), the mean BDI score was 27.6 (s.d. 11.1), and the mean GAS rating was 38.9 (s.d. 8.7).

Using the conventional cut-off for endogenous depression of a Newcastle score greater than 5, patients suffering from endogenous depression ($n=59$) had a significantly higher rate of non-suppression than patients suffering from non-endogenous depression ($n=100$) (47.5% versus 28.0%, $\chi^2=6.16$, $P<0.02$). Moreover, the endogenous depressives were significantly older (45.4 compared with 36.1 years, $t=13.6$, $P<0.001$) were more frequently psychotic (49.1% compared 15.0%, $\chi^2=21.6$, $P<0.001$), and more frequently reported weight loss (72.8% compared 39.0%, $\chi^2=17.1$, $P<0.001$).

We examined the relationship between the DST and Newcastle classification for psychotics and non-psychotics, for patients above and below the median age of 34, and for patients who did and did not report weight loss. For each of these three distinctions, the overall Mantel-Haenszel χ^2 for association was significant. This suggests that these variables, when examined individually, were not responsible for the significant relationship between the Newcastle diagnosis and the DST.

Fig. 1 Relationship between Newcastle scores and DST non-suppression.

Kendell (1982) suggested that two syndromes, such as endogenous and non-endogenous depression, can be distinguished by demonstrating a non-linear relationship between symptomatology and some independent variable such as treatment response, family history, or a laboratory measure. Fig. 1 shows that the association between Newcastle scores and the frequency of DST non-suppression is non-linear. The figure suggests that a cut-off of 4, rather than 5, should be used to distinguish between endogenous and non-endogenous depression. In fact, the 26 patients with a Newcastle score of 4 had a significantly lower non-suppression rate than the 23 patients with a Newcastle score of 5 ($\chi^2=4.45$, $P<0.05$). In comparison

with the findings based on a cut-off score of 5, when a cut-off of 4 is adopted, the non-suppression rate in the non-endogenous depressives is reduced from 28.0% to 20.8%, and the rate in endogenous depressives is slightly increased from 47.5% to 48.8%. When a cut-off of 4 is used, significantly more of the endogenous depressives so defined were non-suppressors (48.8% compared with 20.8%, $\chi^2 = 13.6$, $P < 0.001$). Based on the cut-off score of 4, the endogenous patients are still significantly older (43.8 compared with 35.0, $t = 3.58$, $P > 0.001$), more likely to be psychotic (40.2% compared with 14.2%, $\chi^2 = 13.4$, $P < 0.001$), and more frequently report weight loss (63.4% compared with 39.0%, $\chi^2 = 9.51$, $P < 0.01$). However, none of these variables accounted for the significant association between the DST and diagnosis (all three Mantel-Haenszel χ^2 tests of association were greater than 13.00, $P < 0.001$).

Discussion

Our results replicate the findings of Coppen *et al* (1983) and of Holden (1983), who also found that DST non-suppression was significantly more frequent in endogenous than in non-endogenous depressives, as rated by the Newcastle diagnostic scale. We have extended their results by demonstrating that psychosis, age, and reported weight loss (three variables which have themselves been found to be associated with DST results) are not individually responsible for the significant relationship between non-suppression and endogenous/non-endogenous diagnosis. A cut-off score of 4 maximised the difference between endogenous and non-endogenous groups with respect to DST results. Since the original publication by Carney *et al* (1965), little attention has been given to alternative cut-off scores and their effects on apparent validity.

Since the 1920s, there has been a continuing debate between the dualists, who maintain that endogenous and non-endogenous depression are distinct forms (Gillespie, 1929; Carney *et al*, 1965; Kiloh *et al*,

1972), and the monists, who argue that there is essentially a single disorder, varying only in severity (Mapother, 1926; Lewis, 1934; Kendell, 1969). Several investigators have contributed to this controversy by examining the distribution of symptom scores – a unimodal distribution being viewed as support for the monist position and a bimodal distribution as support for the dualists (Carney *et al*, 1965; Kendell & Gourlay, 1970). Eysenck (1970) cogently argued that the type of distribution is not relevant to the monist-dualist debate, but instead to the separate issue of whether a categorical or dimensional system of diagnosis is more appropriate. More recently, Kendell (1982) noted that a unimodal distribution of symptom scores does not mean that there are no neurophysiological or biological discontinuities. He suggested that a boundary between two syndromes can be established if the relationship between symptomatology and an independent variable is non-linear. We used the DST to search for biological discontinuity. Despite a unimodal distribution of Newcastle scores, their association with the DST was non-linear, and therefore inconsistent with the unitary hypothesis.

The ideal boundary between these groups is another issue. In the present study, a Newcastle score of 4 was the optimal point of discrimination. This finding requires replication both with other independent variables such as family history and follow-up course, and by other investigators using similar independent variables. A two-group classification may not be the most appropriate: cluster analytical studies of depression almost always yield more than two groups (Andreasen *et al*, 1980; Blashfield & Morey, 1979; Paykel, 1971). Examination of other independent variables may reveal that diagnostic groups which are relatively homogenous with respect to DST results are heterogeneous with respect to other aetiological or phenomenological factors.

cis(Z)-flupenthixol decanoate

D I F F E R E N C E

= Proven antipsychotic effect⁽¹⁻⁷⁾

↑ Restores mood⁽¹⁻³⁾

↗ Dosage flexibility

< Cost-effective therapy⁽⁸⁾

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contain cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.

Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.

Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children: Not recommended for children.

Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.

Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusion, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.

Further Information Overdosage should be treated;

(a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

A SCHIZOPHRENIC.

Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.

A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*
haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼ **Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. **Use in Pregnancy:** The safety of haloperidol in human pregnancy has not been established. **Precautions:** Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyl dopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. **Side Effects:** In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). CLOPIXOL®

zuclopenthixol dihydrochloride/zuclopenthixol decanoate

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses.

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 10-50mg/day in divided doses.

Children Not recommended.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients

with Parkinsonism, severe arteriosclerosis, senile confusion states; serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027, 0028, 0029. PA Nos 115/5/3, 4, 6.

CLOPIXOL INJECTION & CLOPIXOL CONC.

INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.

Children Not recommended.

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation

or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.
Package quantities & NHS price (correct of printing) 10 x 200mg (1ml) ampoules £30. 1 x 200mg (10ml) vial £28.63. 5 x 500mg (1l) ampoules £36.23. PL Nos 0458/0017, 0041. PA Nos 115/5/1, 5, 7.

Reduction in Hypochondriasis with Treatment of Panic Disorder

R. NOYES, J. REICH, J. CLANCY and T. W. O'GORMAN

Hypochondriasis was assessed in 60 patients with panic disorder and agoraphobia using the Illness Behavior Questionnaire. Before treatment, IBQ hypochondriasis scores were similar to those of a group of hypochondriacal psychiatric patients. In patients who improved with treatment, significant reductions in somatic preoccupation, disease phobia, and disease conviction occurred. Hypochondriasis appears to be a prominent feature of panic disorder and agoraphobia, and responds to treatment of the primary conditions. Our findings underscore the importance of providing adequate treatment and thereby avoiding wasteful use of medical resources and alienation of patients from doctors.

Hypochondriacal features have frequently been observed in patients with panic disorder and agoraphobia. Buglass *et al* (1977), for example, reported that irrational fear of bodily disease was present in 53% of the agoraphobic women they interviewed, and Harper & Roth (1962) found hypochondriacal worries in 60% of patients with phobic anxiety-depersonalisation syndrome. Similarly, Sheehan *et al* (1980) found that 68% of a series of patients with endogenous anxiety believed they might be physically ill despite medical reassurance, and Noyes *et al* (1980) found evidence of hypochondriacal tendencies in a series of patients with anxiety attacks. Even though the outcome of these patients was quite favourable, 50% acknowledged worry over health, compared with 24% of non-anxious controls. Apart from these observations, there has been little systematic study of the hypochondriasis that occurs in patients with panic disorder and agoraphobia.

An important question is whether the hypochondriacal features in these patients are symptoms of the disorder or traits of personality found among those who develop anxiety disorders. By itself, hypochondriasis is variously regarded. Some consider it a psychiatric syndrome, while others see it as a form of abnormal illness behaviour; still others regard it a cognitive or perceptual style (Bursky & Klerman, 1983). These conceptualisations fall on both sides of the distinction between state and trait: psychiatric disorders are usually regarded as state phenomena, whereas behavioural disturbances and cognitive style are more commonly viewed as enduring traits. The distinction may be important when it comes to treatment; if hypochondriasis is a state phenomenon, then it is more likely to improve with treatment.

Because hypochondriasis may have detrimental effects on the patient-doctor interaction, it is important to know to what extent it can be modified

by treatment (Pilowsky, 1980). In response to their hypochondriacal concerns, patients with panic disorder tend to offer physical symptoms as chief complaints, and this often causes a psychiatric diagnosis to be missed (Katon, 1984). After an initial examination, continuing fears of physical illness often contribute to poor acceptance of the diagnosis and requests for unnecessary investigations (Clancy & Noyes, 1976). The present study was designed to examine the effect of treatment of hypochondriasis as measured by the Illness Behavior Questionnaire (Pilowsky, 1967).

Method

The subjects in this study participated in a controlled trial of alprazolam versus placebo for the treatment of panic disorder at the University of Iowa. They were volunteers recruited by newspaper advertisement, and were screened using the Structured Clinical Interview for DSM-III developed by Spitzer & Williams (1982). All met revised DSM-III criteria for panic disorder (American Psychiatric Association, 1985), and were experiencing at least one panic attack per week. Of the 60 subjects who completed the study, 5 received a diagnosis of uncomplicated panic disorder, 14 had panic disorder with limited phobic avoidance, and 41 had panic disorder with extensive phobic avoidance (agoraphobia). In terms of ICD-9 categories (World Health Organization, 1980), 19 subjects had anxiety states and 41 had phobic states. The median duration of illness was 4.5 years, and the mean age was 36.4 years. Thirty subjects received alprazolam in a mean dose of 5.8 mg/d and 30 received placebo during the eight-week trial.

At baseline and at the end of six weeks on medication, subjects were asked to complete the Illness Behavior Questionnaire (IBQ) developed by Pilowsky & Spence (1975). This self-report questionnaire contains 52 items that deal with patients' attitudes and feelings about their illness, their view of their social situation, and reactions of significant others towards them and their illness. Fourteen of

3 Males and females combined

the items, known as the Whiteley Index, have been shown to discriminate between hypochondriacal and non-hypochondriacal patients (Pilowsky, 1967). The Hamilton Anxiety Rating Scale (HARS) was also administered at baseline and weekly during the period of drug administration (Hamilton, 1959). Subjects who showed a decrease of 5 or more points on the HARS were considered to have improved. By this criterion, 32 subjects (14 men and 18 women) improved, and 16 subjects (8 men and 8 women) did not. Mean HARS scores for the improved subjects were 20.3 at baseline and 6.6 at six weeks. Mean scores for unimproved subjects were 18.4 and 19.4.

In order to examine the effect of improvement on the IBQ, we compared the number of improved subjects answering 'yes' to an item at baseline and 'no' to that item at six weeks with the number answering 'no' at baseline and 'yes' at six weeks. Subjects answering a question the same way on both occasions were excluded from the analysis. The sign test was used to examine the probability of obtaining the observed responses, assuming that subjects had an equal chance of responding in one of the two sequences described.

Results

Subjects with panic disorder obtained relatively high scores on the Whiteley Index. The mean number of hypochondriacal items affirmed by panic disorder subjects at baseline was 7.2 (s.d. 2.9), compared with 1.7 (s.d. 2.4) for a small series of normal subjects previously reported. Table I provides a comparison of scores on the Whiteley Index obtained from several groups, including hypochondriacal and non-hypochondriacal psychiatric patients, patients with malignant disease, and normal subjects, all reported by Pilowsky (1967). It shows mean baseline scores for male and female panic disorder patients that were nearly as high as those for hypochondriacal psychiatric in-patients. At baseline, a substantial proportion of panic disorder subjects affirmed items belonging to the dimensions of hypochondriasis measured by the 14-item scale, including bodily preoccupation, disease phobia and disease conviction (Table II).

A statistically significant reduction in scores on the Whiteley Index was observed after six weeks of treatment with alprazolam. Among improved subjects the mean fell from 7.2 (s.d. 2.9) at baseline to 4.4 (s.d. 2.9) after six weeks ($P < 0.0001$). In subjects who failed to improve, no statistically significant change occurred: the means were 6.6 (s.d. 4.0) at baseline and 5.6 (s.d. 4.6) after six weeks. Scores for three dimensions of hypochondriasis obtained by previous factor analysis were also significantly reduced in improved subjects after six weeks (Pilowsky, 1967). The mean score for bodily preoccupation (four items) dropped from 2.1 (s.d. 0.9) to 1.2 (s.d. 1.0) ($P < 0.01$), the score for disease phobia (three items) fell from 2.2 (s.d. 1.2) to 1.6 (s.d. 1.2) ($P < 0.02$), and that for disease conviction (three items) changed from 1.0 (s.d. 0.9) to 0.5 (s.d. 0.6) ($P < 0.01$).

Statistically significant changes were observed between baseline and six weeks on eight items dealing with bodily preoccupation, disease phobia and disease conviction (Table II). Many represented nearly 50% reductions in the proportion of subjects who reported 'worry about health', 'worry about serious illness', 'worry about disease brought to attention', 'something seriously wrong with body', 'bothered by many different symptoms' and 'bothered by many aches and pains'. Significant reductions at six weeks were also seen in 'silly thoughts about health', 'something seriously wrong with mind', 'more susceptible to illness than others' and 'upset with appearance'.

In contrast to this, relatively little change was seen in the proportion of subjects reporting interpersonal alienation as a consequence of illness. As is shown in Table II, treatment had relatively little effect on the response to three hypochondriacal items from the Whiteley Index having to do with interpersonal interactions surrounding illness: 'illness not taken seriously by others', 'annoyed by being told you look better' and 'hard to believe the doctor that there is nothing to worry about'. When we examined the response of improved subjects to all the items that might reflect interpersonal alienation, including several suggesting alienation from doctors, we found that although the response to 13 of the 16 items decreased with treatment, only one, 'illness affects getting along with others', showed a statistically significant reduction.

TABLE II
Response of improved subjects to the Whiteley Index: percentage answering "yes"

	Baseline	Six weeks
<i>Bodily preoccupation</i>		
Aware of bodily sensations	84.4	65.6*

Discussion

Our findings proved confirmation of a high level of hypochondriasis in subjects with panic disorder and agoraphobia. In fact, the scores we observed using the Whiteley Index of the IBQ were nearly as high as those previously obtained from a group of psychiatric patients that had been selected for hypochondriacal features. Also, the response to individual items from the IBQ indicates that a substantial proportion of persons with panic disorder and agoraphobia experience bodily preoccupation, disease phobia, and disease conviction, all of which are major characteristics of hypochondriasis (Pilowsky & Spence, 1983). In our population, these features were present despite repeated reassurance from doctors concerning the absence of physical disease.

We have demonstrated that the hypochondriasis associated with panic disorder and agoraphobia responds to treatment. A substantial reduction in IBQ scores was observed after six weeks of treatment, and this was accompanied by a clinically apparent decrease in hypochondriasis. Indeed, many subjects reported that treatment had relieved their preoccupation with bodily sensations, their fear of physical disease, and their belief that they might be

physically ill. An examination of individual items showed that these dimensions of hypochondriasis were all strongly influenced by the treatment. Because responses to the IBQ remained relatively stable among unimproved subjects, it is unlikely that non-specific factors such as repeated testing, medical contact, or emotional support could account for the changes found. In fact, the observed effect might have been greater had anxiety symptoms been eliminated by the treatment administered; some patients remained symptomatic despite substantial improvement.

There are several possible explanations for the association between anxiety and hypochondriasis observed in this study. The first is that anxiety may be associated with distorted cognitive assessment of health status. This possibility is supported by Beck *et al* (1974), who found anticipation of physical harm proportionate to the level of anxiety in patients with anxiety disorders. A second possibility is that anxiety may be accompanied by a state of heightened alertness, resulting in greater awareness of physiological processes; this possibility is supported by Tyrer *et al* (1980), who found anxious patients to be more aware of their heartbeats than normal controls. Anxiety may also be associated with physiological

arousal—a third possibility that is supported by physiological investigations (Lader, 1978). Autonomic nervous system activation can produce symptoms causing anxious patients to suspect malfunction of many organs, including the heart. In fact, all three of these possibilities have been described as mechanisms contributing to hypochondriasis (Bursky & Klerman, 1983).

Our findings suggest that the association between hypochondriasis and panic disorder may be an intimate one; hypochondriasis may in fact be an inherent aspect of the anxiety syndrome. Various authors have noted that hypochondriacal concerns are a consistent part of the clinical picture of anxiety states (Harper & Roth, 1962; Buglass *et al*, 1977; Noyes *et al*, 1980; Sheehan *et al*, 1980). Also, during panic attacks patients describe an overwhelming experience of hypochondriasis; at the height of an attack some patients report not only intense fear but a belief that their death, due to some catastrophic event, is imminent. This belief is based on the symptoms of a massive sympathetic discharge that suggests impending collapse. Many patients go to the nearest emergency room in search of life-saving interventions. All this occurs despite medical reassurance, and represents hypochondriasis in its most intense form.

It is clear from this study that the measurement of hypochondriasis is influenced by state anxiety. This means that valid assessment of hypochondriasis in panic disorder patients must take the level of anxiety, and perhaps depression, into account. Completely eliminating state anxiety in such patients may be difficult because of the chronicity of the disorder. With modern drug treatment, however, a proportion of patients become virtually free of symptoms, at least for the duration of the treatment. Consequently, re-

search to determine whether hypochondriasis is unique to anxiety disorders and the extent to which it is state-dependent in such patients appears to be possible. A comparison of anxious and depressed patients should yield information on the question of specificity.

Our findings underscore the importance of adequate treatment for patients with panic disorder and agoraphobia. They show that hypochondriasis is a treatment-responsive feature of this illness. Without treatment, hypochondriasis often leads to repeated consultations, examinations and laboratory evaluations in search of a physical explanation for symptoms (Clancy & Noyes, 1976). These activities not only waste medical resources but often leave patients even more hypochondriacal than before. Hypochondriasis is a stumbling block to the diagnosis and management of disorders that effective treatment might remove.

Our anxious patients, reported a degree of interpersonal alienation that diminished only slightly with a lessening of their anxiety. These patients typically reported that others do not regard them as ill or take their illness seriously; indeed, their own attitude towards their condition is often changeable and uncertain. At one moment they believe themselves to be seriously physically ill, while at the next they suspect that they are not ill at all, and should simply get control of themselves.

Successful treatment of anxiety disorders needs to take the hypochondriasis of the patients into account.

Psychogenic Skin Disease: A Review of 35 Cases

N. P. SHEPPARD, S. O'LOUGHLIN and J. P. MALONE

In three years of clinical practice, the authors saw 35 cases of dermatological disorders of strictly psychological origin—8 patients with *dermatitis artefacta*, 8 with delusional parasitosis, and 19 who presented with skin complaints but showed no dermatological pathology ('dermatological non-disease'). All but two initially presented for dermatological opinion rather than psychiatric assessment, and 12 refused psychiatric referral. Demographic and clinical details of all 35 cases are given, including possible related factors, course, treatment, and outcome, and the cases are discussed in the context of the existing literature. Liaison between dermatologists and psychiatrists is strongly advocated.

The association between disorders of the psyche and those of the skin has been extensively studied. Evidence has been produced suggesting a higher prevalence of psychiatric disorder in dermatology out-patients and in-patients than in the general population and the general medical in-patient population respectively (Hughes *et al*, 1983).

A variety of mechanisms have been postulated as being of aetiological importance in psychogenic skin disease. These range from classical Freudian ideas of hysterical conversion mechanisms to ideas of the skin as an infantile preverbal means of communicating emotions which is brought back into operation at times of regression, or is repeatedly utilised by those who have failed physically or psychologically to develop the language to express feelings. There are also biological theories of specific neurophysiological disturbances.

In a review of psychosomatic aspects of dermatology, Koblenzer (1983) has offered a working classification for psychocutaneous disease which emphasises approach to treatment. She lists three main categories of conditions:

1. Conditions that are strictly psychological in origin
2. Conditions in which strong psychogenic factors are imputed, e.g. chronic urticaria and hyperhidrosis.
3. Conditions that are dependent on genetic and environmental factors, but in which the course of disease is substantially affected by stress, e.g. psoriasis, atopic dermatitis, and recurrent herpes simplex.

Eller (1974) describes a fourth category, i.e. skin disorders that are likely to affect the psyche, e.g. those associated with disfigurement, chronic pain, or itching.

In the first category, with which this paper is concerned, Koblenzer includes conditions such as *dermatitis artefacta*, delusions related to the skin, psychogenic purpura syndrome, and dermatological non-disease. Although these disorders occur relatively infrequently, early recognition is important for several reasons. Investigation of them is often extensive, repeated, and highly expensive, and may be a strong reinforcer of what can be regarded as abnormal illness behaviour. Ultimately, however, their prime importance lies in the fact that they may be a source of severe distress and extreme social disruption to those who suffer from them. It is our experience with this group of patients that we wish to describe.

Method

Patients with conditions falling into the first of Koblenzer's categories were collected by the authors in the course of their ordinary clinical practice over a three-year period. In all, 35 such patients were seen. The vast majority (all but two) had initially presented for a dermatological opinion rather than psychiatric assessment. Data on sex, occupation, age at presentation, nature and duration of symptoms, possible related factors, course, and outcome were obtained.

Patients were allotted to three main diagnostic groups:

- (i) *Dermatitis artefacta*, which may be defined as any form of self-inflicted skin injury in which the patient denies producing the lesions (Eller, 1974)
- (ii) *Delusional parasitosis*, in which patients have an erroneous but unshakeable belief that their skin is infested by parasites (Gould & Gragg, 1976)
- (iii) *Dermatological non-disease*, a common and serious disorder of cutaneous body image in which the patient presents with dermatological complaints but with no significant dermatological pathology on examination.

TABLE I
Summarized case histories of eight patients with dermatitis artefacta

Case number	Sex	Marital status	Occupation	Age (years)	Duration of symptoms	Type of lesion	Possible related factors	Outcome
1	F	Single	Bank official	35	3 months	Bruising and swelling of right knee	Previous episode of hysterical aphonia after father's death Frustrated career ambitions	Lesions cleared on occlusion, but further lesions developed which also cleared up. Refused psychiatric help
2	F	Married	Housewife	30	3 months	Ulcer on right ankle and below right knee	Previous treatment for depression after discovery of husband's infidelity with patient's sister	Lesions cleared in hospital; re-admitted one month later with further lesions. Cleared on occlusion Seen by psychiatrist, who treated her for depression
3	F	Single	Waitress	49	2 months	Erosive, weeping, non-pruritic malar rash	Work problems Content to remain in hospital	Initially treated as a secondary bacterial infection superimposed on a herpes simplex infection: no response. After six weeks, patient was observed by staff scratching lesions with a coat hanger. On confrontation, patient denied factual element and refused psychiatric referral. Lesions healed in one week
4	F	Married	Housewife	67	10 years, recurring	Sharply demarcated ulcer, dorsum of left hand	Long history of endogenous depression in a vulnerable personality, with a variety of environmental factors (including diabetes mellitus and family dysharmony) aggravating the situation	Lesion healed on occlusion
5	F	Single	Schoolgirl	10	14 months	Temporo-parietal hair-loss	History of school difficulty	Diagnosed as trichotillomania. Referred to child psychologist. Partial improvement after family therapy
6	F	Married	Housewife	?	2 months	Blisters on chest	Long history of marital dysharmony. Recently upset by a planned wedding in the family	Initially diagnosed as pemphigus. Attempted to enlist daughter to bring a bottle from home into hospital: husband intervened and discovered it was paranoiac. Discharged herself before a psychiatric evaluation could be carried out
7	F	Single	Unemployed	29	9 years	Purpura, painful, occurring spontaneously over a few hours, usually involving arms, legs, occasionally trunk, but sparing face	Dull, immature girl with restricted social life and dependent relationship with relatives, conflict re illegitimacy, family history of affective disorder	Initially queried as Gardner Diamond syndrome, but negative result to injection of autologous blood. Continued observation revealed factual aetiology. Referred for psychotherapy
8	F	Single	Schoolgirl	16	6 months	Bruising of right arm, shoulder to elbow	Bruising started following a fall on ice, when she injured an elbow. Subsequent crops of non-painful bruises, did not occur in any other site All investigations negative	Initially diagnosed as Gardner Diamond syndrome on clinical grounds. Injection of autologous blood not performed. Subsequently, diagnosis changed to factitial disease Refused psychiatric referral

TABLE II
Summarised case histories of eight patients with delusional parasitosis

Case number	Sex	Marital status	Occupation	Age (years)	Duration of symptoms	Nature of infestation	Possible related factors	Outcome
1	F	Married	?	48	?	"Things crawling all over me"	Previous history of recurrent visions of Christ and presence of stigmata on her hands 12-year history of unexplained pruritus vulvae	Seen initially by psychiatrist, who diagnosed "Hysterical, no treatment needed". Subsequently seen by dermatologist, who diagnosed delusional parasitosis
2	M	Single	Unemployed	54	2 years	Lice, initially in eye-brows but later spreading over entire body		Not seen by psychiatrist. Partial response to pumozide
3	M	Single	Accountant	56	15 years	Fleas, two varieties resembling wood-lice	History of early paternal loss, work difficulty, and residual disability after polio	Seen by psychiatrist, who diagnosed monosymptomatic encapsulated delusional disorder. Good response to pumozide and imipramine
4	F	Married	Retired teacher	79	6 years	Insects biting and itching	Estranged from family because of delusions. Moved from house for fear of contaminating family	Not seen by psychiatrist. Fully cured after direct firm confrontation by dermatologist
5	M	Single	Farmer	30	1 year	Insects infesting glans penis	Dull normal intelligence. Planning marriage. Guilt feelings re previous history of bestiality	Refused psychiatric help
6	M	Single	Labourer	62	2 years	Insects crawling under his skin	Previously diagnosed as hairy cell leukaemia. Referred by haematologist to dermatology clinic with a skin rash caused by applying TCP to his skin several times a day. Had been spraying his room with insecticides and insect repellants	Refused psychiatric intervention. Problem persists
7	M	Single	Unemployed	62	3 months	Lice crawling over him. O/E rash secondary to excoriation and application of disinfectants	Blind. Previous history of recurrent depression and alcohol abuse. Seen by dermatologist. Diagnosed as "neurodermatitis"	Resolved with treatment of depression
8	F	Widow	Housewife	52	3 months	"Live things" coming from her legs, which "could milk too much oil out of my skin in the bath". Produced a matchbox of "parasites"; in reality skin squames	Widowed and socially isolated. History of streptomycin-related hearing impairment	Accepted psychiatric referral. Depression diagnosed. Improved on antidepressant medication

TABLE III
Summarised case histories of 19 patients with dermatological non-disease, grouped according to symptomatology (facial/scalp or hair/genital/other)

Case number	Sex	Marital status	Occupation	Age (years)	Duration of symptoms	Nature of symptoms	Possible related factors	Outcome
Facial								
1	M	Single	Teacher	28	3 years	Facial redness O/E N.A.D	Long-standing ambivalent relationship with mother. Career problems. Marked obsessional traits	Minimal improvement with brief psychotherapy
2	M	Single	Factory worker	24	5 years	Facial redness. O/E N.A.D	Felt colleagues and girlfriends repeatedly remarked on his face. Anxious, sensitive, with marked feeling of inferiority	Refused psychiatric referral. No improvement after two years
3	M	Single	Farmer	25	3 years	Facial redness. O/E N.A.D	Aggravated by stress. Socially embarrassing. No response to topical steroids and tetracycline	Refused psychiatric help. Self-referral to a Harley Street plastic surgery clinic, where he was offered dermabrasion
4	F	Single	Secretary	46	"Several years"	Facial redness and tingling	Socially withdrawn. Previous history of depression treated with antidepressants	Some improvements with supportive measures
5	F	?	?	55	20 years	Facial burning		Refused psychiatric help
6	M	Married	Cook	35	15 years	Nose red and mis-shapen. O/E N.A.D.	Previous plastic surgery, 10 years before, felt it made him worse. Wanted further surgery	Depressed and anxious. Refused psychiatric help. No change after two years
Scalp/hair								
7	M	Single	Trainee accountant	25	"few years"	Scalp soreness. O/E N.A.D	Aggravated by stress. Associated loss of interest in work. Mother had history of a similar complaint some years previously during a stressful time	Accepted psychiatric referral, but symptoms had resolved when seen
8	N	Single	Salesman	20	8 months	Scalp tenderness and hair loss. O/E N.A.D.	Marked anxiety symptoms related to seeking work	Symptoms improved as anxiety abated
9	M	Single	Civil servant	21	1 year	Hair loss. Hot stinging of scalp on entering warm environment. O/E N.A.D.	History of neurotic traits in childhood. Blamed a "bad haircut". Career dissatisfaction	Seen by psychiatrists. Symptoms noted as "almost delusional in intensity". Improved without treatment, although remained convinced that a change had occurred
10	M	Single	Trainee pilot	22	2 years	Hair loss. O/E N.A.D.	Originally from Libya, working in Ireland for 2 years. Home-sick and lonely	Improved with reassurance and support

TABLE III
Continued

Case number	Sex	Marital status	Occupation	Age (years)	Duration of symptoms	Nature of symptoms	Possible related factors	Outcome
11	M	Single	Unemployed	43	16 years	Hair loss O/E male pattern baldness	Pre-occupied with hair loss. Had sought numerous dermatological opinions. Quit work and had been housebound for 15 years, enabled by over-protective, over-involved parents. Referred to psychiatrist for assessment for disability pension	Saw psychiatrist, but refused intervention
12	F	Single	Unemployed	30	Several years	Hair loss. O/E N.A.D.	Previously diagnosed and treated for schizophrenia	No improvement
13	F	Widow	Unemployed	53	1 year	Change in texture and colour of hair	Blamed change on a "bad perm"	Accepted psychiatric referral. Diagnosed as severe endogenous depression. Scalp symptoms fluctuate with mood, but still persist
Genital								
14	M	Married	Traveller	50	2 years	Scrotal itch and redness	Marked anxiety precipitated by guilt over extra-marital sexual contact	No marked improvement with reassurance
15	M	Married	Mechanic	55	1 year	Penile itch and redness	Guilt over extra-marital sexual contact. Concerned that he had contracted genital herpes	Improved with reassurance
16	M	Single	Farmer	23	?	Scrotal itch and burning	Anxiety <i>re</i> previous sexual contact. Feared he had a venereal disease	Improved with reassurance
17	M	Single	Fitter/welder	26	2 years	Scrotal itch	Anxiety <i>re</i> previous sexual contact. Feared he had a venereal disease. Marked obsessional traits	Accepted psychiatric referral. Currently attending psychiatrist
Miscellaneous								
18	M	Single	Medical student	22	2 years	Emitting foul odour. O/E N.A.D.	Felt friends had withdrawn because of odour	Refused to accept diagnosis. Diagnosed as personality disorder. Refused advice or psychiatric referral
19	F	Married	Housewife	34	1 year	Excessive axillary sweating. O/E N.A.D.	Associated severe anxiety symptoms. Wanted surgery for her problem	Refused advice or psychiatric referral

Results

We saw eight patients with artefactual skin disease (Table I). All eight were female. Age at presentation was ascertained for seven of the patients and ranged from 10 to 67 years, with a mean age of 29.5 years. The duration of symptoms at time of presentation ranged from two months to 10 years. The nature of the lesions varied from patient to patient, but included bruising, blistering, ulceration, skin rashes, and hair loss. All the lesions healed after occlusion, close observation of the patient, or confrontation.

Of eight patients presenting with delusions of infestation (Table II), five were male. Age at presentation ranged from 30 to 79 years, with a mean of 55.4 years. The duration of symptoms was determined in seven cases, and ranged from three months to 15 years, with an average of 4.4 years. Two patients had extensive previous psychiatric histories, and all had suffered marked social disruption because of their symptoms. Two patients were treated with pimozide, and showed some improvement.

We saw 19 patients with dermatological non-disease (Table III)—14 of whom were male. Age at presentation ranged from 20 to 55, with a mean of 30.7 years. Duration of symptoms was calculated accurately in only 14 cases: it ranged from eight months to 20 years, with a mean of 5.3 years. Symptomatology fell into three main groups: (1) facial symptoms; (2) scalp and hair symptoms; and (3) genital symptoms. Psychiatric diagnoses in these cases of dermatological non-disease included dysmorphophobic disorder, schizophrenia, major affective disorder, and anxiety states.

Discussion

Dermatitis artefacta

It is characteristic of *dermatitis artefacta* that the lesions, single or multiple, are bizarre in configuration and appearance, and are confined to areas accessible to the hands. A variety of means may be used to produce the lesions: noxious substances may be applied, or the angular border of a lesion may suggest the nature of the instrument used to produce it. Diagnosis is confirmed by showing that the lesions heal under efficient occlusion.

Rather than regarding *dermatitis artefacta* as an isolated syndrome, most authorities now see it as part of a wide spectrum of self-induced disease. Sneddon & Sneddon (1975), in their follow-up study of 43 patients with self-inflicted skin-lesions, showed that in the majority of cases, *dermatitis artefacta* was only one episode in a long history of psychogenic illness, and noted that recovery was linked to changes in patients' life circumstances rather than to formal treatment. In our series, four patients had previous histories of formal psychiatric problems (two with depression and one each with hysterical conversion and school refusal), while all eight were under signifi-

cant psychological stress at the time of production of their symptoms.

Lyell (1976) has reviewed possible reasons for the reluctance of doctors to make a diagnosis of *dermatitis artefacta*. They include an inability to believe that patients, especially the respectable and the intelligent ones, might wilfully deceive them; while fear of missing organic disease (coupled with the fact that the bizarre lesions suggest rare diseases or unfamiliar manifestations of more common ones) leads the doctor to continue the search for a physical cause. This is amply illustrated by Case 1, in which the patient had approximately £2000-worth of consultations and investigations before the correct diagnosis was arrived at.

Psychogenic purpura syndrome (Gardner-Diamond syndrome) was considered in the differential diagnosis of two cases (7 and 8) listed in Table I. This is an unusual and rare syndrome, distinguished by crops of painful ecchymoses and multiple systemic complaints. It was first described by Gardner & Diamond (1955). They were impressed that their patients (four women) had sustained physical injuries shortly before the onset of symptoms. They postulated that as a result, the patients had become sensitised to their own erythrocytes, and that subsequent extravasation of blood during the unrecognised trivial injuries of everyday life induced the purpuric lesions. Gardner & Diamond reproduced the typical bruises of what they called 'auto-erythrocyte sensitisation' by the intracutaneous injection of the patients' own blood, determining that the factor responsible for the reaction was present in the red cell stroma. Ratnoff & Agle (1968), re-evaluating the syndrome, commented on the severe emotional disturbances antedating the first purpuric lesions in all their patients. Furthermore, in a third of the patients they studied, the lesions could not be reproduced by injection of autologous blood. Ratnoff & Agle felt that the psychological factors might play a critical role in pathogenesis, and suggested renaming the syndrome 'psychogenic purpura' syndrome. As mentioned previously, this diagnosis was considered in two cases in our series, initial symptomatology in both cases corresponding closely to descriptions of the condition in the literature. However, the diagnosis was rejected on both occasions when continued observation led to direct evidence of a factitious aetiology.

Delusional parasitosis

The term 'delusional parasitosis' is preferable to older terms such as 'parasitophobia' and 'acaraphobia', which have been criticised for implying a

phobic rather than a delusional mechanism underlying the condition, and because a variety of infective agents other than acari are implicated by the patients.

The typical patient with delusional parasitosis is aged 40 or over and is female, the sex ratio being generally reported as 3:1, although five of the seven patients in our series were males. Patients usually present with detailed descriptions of the insects and of their burrowing, biting, or otherwise harming the patient. There may be physical evidence of excoriation or the use of antiseptics to eradicate the infestation, and the patients often produce spurious 'samples' in support of their claims. Patients frequently seem antagonistic towards medical staff, and vehemently oppose suggestions that they might be mistaken or that they should seek psychiatric help.

It has been maintained that there is a difference between patients who initially present to a dermatologist and those who are referred directly to a psychiatrist, the latter being more likely to have a recognisable psychiatric disorder. However, allocation of these patients to distinct psychiatric categories has been generally noted to be difficult, with patients receiving diagnoses as varied as affective disorder, paranoid schizophrenia (mostly older patients), and monosymptomatic hypochondriacal psychosis.

In making a diagnosis of delusional infestation, the necessity of ruling out actual infestation or organic illness such as vitamin B₁₂ deficiency, pellagra, or disseminated sclerosis needs to be stressed. Having said this, patients with delusional parasitosis are notoriously difficult to treat. Gould & Gragg (1976), rejecting earlier more pessimistic attitudes to treatment, have suggested sensible guidelines for the psychological management of these patients, primarily by the dermatologist. This model is essentially one of simple supportive psychotherapy. More recently, reports of successful treatment of the condition with pimozide have appeared (Riding & Munro, 1975; Reilly *et al.*, 1978). Delusional parasitosis has been well reviewed by Munro (1980).

Dermatological non-disease

The importance of the condition called 'dermatological non-disease' lies in the extreme distress it causes the patient. It may be socially crippling, and on occasion results in suicide. Patients may spend small fortunes in pursuit of a 'cure'.

Cotterill (1981), in a review of 28 patients with dermatological non-disease, found that in general, symptomatology was confined to three main sites—

the face, the scalp, and the genitalia. Only two of his patients presented with symptoms outside these areas. The distribution of the symptomatology amongst our series of patients was similar: six patients with complaints of facial abnormality, seven with scalp complaints, and four with genital complaints. Of the two remaining patients, one complained of abnormal body odour and the other of excessive axillary sweating.

The commonest facial symptoms in Cotterill's group were complaints of itching and burning, and a preoccupation with imagined facial hair. He noted this sub-group to be predominantly female, and felt they had the most ominous prognosis, three of his patients ultimately committing suicide. Of our own group of six patients reporting facial symptoms, four were male. They complained mainly of facial redness, with tingling and burning in some cases.

Amongst our group of patients with scalp symptoms, the commonest complaints were of excessive hair loss, and tingling or itching of the scalp. This is in keeping with Cotterill's experience. One patient who was subsequently diagnosed as having severe endogenous depression complained of a change in the colour and the texture of her hair. It is interesting to note that this patient and one other dated their symptoms from visits to hairdressers whose work they were dissatisfied with.

All four of our patients with genital symptoms were male. The commonest complaint was of scrotal itching, and in each case the symptom appeared to have been precipitated by a sexual encounter which had left the patient feeling guilty. All four initially feared that they had contracted a venereal disease. Symptoms improved with reassurance in two cases, but persisted in the remaining two. Again, these findings are very much in line with those of Cotterill (1981).

Cotterill noted that the majority of his patients could initially be given a diagnosis of dysmorphophobia. This is a condition in which sufferers become concerned and preoccupied with some external physical defect which they think is noticeable to other people, whereas objectively speaking they have no cause for complaint, their appearance being well within normal limits. It is essentially a disorder of the 'psychological' body-image (Hay, 1970). The question of whether dysmorphophobia involves a delusional conviction or a neurotic, hypochondriacal preoccupation has been extensively debated. In his review on the subject, Hay concluded that dysmorphophobia as a symptom was non-specific, that it could occur in different psychiatric syndromes, and that it was prone to occur in subjects with sensitive or insecure personalities. Cotterill stressed that the

commonest final psychiatric diagnosis in those with scalp symptoms was depressive illness.

Conclusions

Far from regarding these conditions as exotic rarities, we feel that they form an important and common cause of psychiatric morbidity (particularly dermatological non-disease). As mentioned above, early recognition and intervention is important. Who

should be the primary agent in the treatment of these patients? The fact that most of the literature concerning these disorders is to be found in the dermatological rather than the psychiatric literature emphasises the reluctance of many of these patients to avail themselves of psychiatric help, and the efforts of dermatologists to offer psychological help. We feel that this is an important area where liaison between psychiatrist and dermatologist can only benefit the patient.

A Clinical Study of Gilles de la Tourette's Syndrome in Korea

Clinical data on 30 Korean patients of the authors with Gilles de la Tourette's syndrome are described, as well as data on seven other Korean cases from the literature. The overall characteristics and EEG findings were similar to those of Western patients, but there were fewer obsessive-compulsive behaviour problems, and family histories were less often positive.

Gilles de la Tourette's syndrome is an unusual condition, characterised by the onset in childhood or adolescence of recurrent, involuntary, repetitive, and rapid movements which include multiple vocal tics. Coprolalia, copropraxia, echo-phenomena, and obsessive-compulsive traits may also be present, but are not diagnostic prerequisites. Aetiologically, it has been considered at least partly a psychogenic disorder, but neurophysiological studies suggest that its basis is neurological (Shapiro & Shapiro, 1982), while Lees *et al* (1984) have reported evidence for heterogeneity.

Although many cases have been reported in western countries over the past 100 years, there have been fewer than fifty from Asia in the English-language literature. Only about ten reports of Asian cases could be found in the Australian MEDLARS and in Index Medicus. Although one was reported in India in 1962, the first Asian case is generally thought to be that of a Chinese boy in Hong Kong (Singer, 1963). The scarcity of such reports does not necessarily reflect the rarity of the syndrome, but rather the lack of awareness of it, and failure to publish cases in English-language journals (Lieh-Mak *et al*, 1978).

In Korea, six cases have been published since Lee & Sul (1968) reported the first case (that of a seven year-old girl); all of these were in Korean medical journals only. Suh & Park (1969) reported a 14 year-old boy with the syndrome who had suffered from sibling rivalry and a domineering and punishing father. Kim (1971) described a ten year-old boy, in whom the aetiological factors were said to be hostile identification and ambivalence to a father figure and an unconscious desire for self-punishment. Koh *et al* (1971) reported a 20 year-old male, whose typical symptoms improved with phenothiazine. Rhee & Kim (1973) described a 27 year-old male, in whom the aetiological problems were postulated as hostility and poor impulse control towards authority figures; he had also a typical obsessive-compulsive disorder, and haloperidol was used for the first time in Korea in this case. Kim & Lee (1973) reported a 20 year-old female, and Kang & Yoon (1974) a 14 year-old boy who has had phobias and compulsive behaviours;

psychodynamic factors were described as a tyrannical father figure and feelings of rejection.

In this report, we summarise the clinical data on 30 Koreans with the syndrome whom the authors have seen personally since 1976, along with additional data from the seven cases described above.

Method

Thirty patients were diagnosed as having Gilles de la Tourette's syndrome during the period 1976-1984 at the Department of Psychiatry, Yonsei University Medical Center, Seoul. All were evaluated psychiatrically by one of the authors, history of symptoms and family and developmental history were also obtained from semi-structured interviews with the patients and their families.

For final inclusion, all clinical data were reviewed again by both authors for the following diagnostic criteria: onset of symptoms between the ages of 2 and 15; presence of recurrent, involuntary, repetitive, rapid, purposeless motor movements, affecting multiple muscle groups; and multiple vocal tics. Ability to suppress movements voluntarily for minutes or hours, variations in the intensity of symptoms over weeks and months, and duration of more than one year, as required by DSM-III (American Psychiatric Association, 1980), were not considered necessary for the diagnosis; neither was coprolalia.

Twenty-nine patients met these criteria. In a further female patient, the syndrome began at the age of 18. Her symptoms, such as barking and multiple tics, were typical of the syndrome, had been present for about four years, and were controlled by haloperidol. She was therefore diagnosed as having Gilles de la Tourette's syndrome, and included in the study.

Eight of the cases were referred by neurologists, neurosurgeons, paediatricians and physicians, and nine by other psychiatrists in the same department.

Results

All 30 patients were native Korean citizens. The syndrome appears to be rare in Korea, considering that the total number of out-patients of this Medical Centre was about four million during the period. Twenty-four patients were males and six females. The average age was 11.8 years, and ranged from 6 to 32; 24 patients were in the range 8-16 years. One of the four adults was married.

No significant factor was reported in the birth history of any patient, but 15 had an abnormal developmental history, including hyperactivity and distractibility in nine cases, learning difficulties in four, enuresis in two, encopresis in one, and stuttering in two. Twelve patients were reported by parents to have irritable and impulsive personalities, eight to be competitive and egocentric, five to be obsessive and meticulous, and five to be shy and polite.

As far as the medical history was concerned, two patients had suffered from nephritis, two from dog bites, two from pulmonary tuberculosis, one from a car accident, and one from febrile convulsions. One patient had had a tonsillectomy. These previous problems did not seem to play a role in the initiation of the symptoms.

Ten patients were the youngest of their families, six were in between more than three siblings, four were oldest sons, and eight were only sons or daughters. Simple tics were reported to have been present in the siblings of only two patients. The presence of functional psychosis in first-degree family members was denied in all cases except one, where the grandmother died of an unspecified psychosis.

The syndrome began before the age of 15 in 29 cases and at age 18 in one female, who can be considered as an example of an adult-onset type of the syndrome. The mean age of onset was 8.7 years for males and 7.8 for females, while the commonest age of onset was between two and four years (eight patients). The mean duration of the illness was 3.8 years (range 0.1–22 years).

Various precipitating and situational factors might reflect psychodynamic influence on the development of symptoms, e.g. tonsillectomy in two cases, and beating by the father, elder brother, or schoolteacher in four cases. Eleven other cases were thought to show psychogenic factors, including emotional frustration, conflicts in child-parent relationships, and loss of self-esteem; two patients scarcely showed the symptoms at school, but frequently did at home.

Most patients reported that the symptoms, especially vocalisations, were usually aggravated by anxiety, tension, and other emotional stress. Fifteen reported anxiety, emotional uneasiness, and chest tightness when they tried to voluntarily control or inhibit symptoms—especially with coprolalia in four cases. Common cold with fever seemed to be related to recurrence in six cases.

After the initial symptoms, other parts of body became involved, and new tics developed which replaced or added to pre-existing ones; the general progression was cephalocaudal. These symptoms are shown in Table I. Obsessive-compulsive personality traits were noted in five patients, but such behaviour, e.g. touching and changing clothes, was reported in only three of these.

Only nine cases showed the classical syndrome with multiple motor tics, barking, and coprolalia; another eight had combined multiple motor tics and barking. Nine cases had multiple motor tics and other vocalisations, while four had only severe multiple motor tics. According to the criteria of severity of Shapiro *et al* (1973), 14 patients (47%) were rated as having marked and severe illness, i.e. progressive and chronic, without remission, and with serious social, academic, and occupational impairments.

No patients were evaluated as having schizophrenia or other psychoses. Ten children were reported to have

TABLE I
Initial and presenting symptoms in 30 Korean cases with Gilles de la Tourette's syndrome

Symptoms	Number of patients	
	Initial	Presenting
Eye twitchings	15	16
Tongue movements		3
Grimaces	4	9
Barking		14
Other vocalisations	4	9
Head and neck jerks	6	20
Arm jerks		12
Leg jerks		10
Trunk jerks	1	5
Coprolalia		9
Spitting		5
Echolalia		4
Compulsive behaviours		3
Stuttering		2
Bizarre mannerisms		2

marked adjustment reactions to peer relationships at school since the onset of the syndrome, e.g. one eight year-old boy refused to attend school because of teasing by peers. Two patients had suffered from nightmares. Four patients, who were older, were diagnosed as having reactive depression; one of them, a 17 year-old male, showed serious depression with suicidal ideas. The parents of six children reported that the personality of their children had changed since the onset of the syndrome to become hyperactive, violent, and impulsive.

Thirteen of 25 patients who had EEG examinations showed non-specific abnormal findings: random slow waves in three cases, random slow and sharp wave mixtures in five, mild focal abnormality in one, and a burst of high amplitude sharp waves in both hemispheres in four. Computerised tomography was carried out in six cases, and the findings were normal in all these.

Among previous treatments were anticonvulsant medication in five cases diagnosed as having a myoclonic epilepsy before referral, benzodiazepines in three, herbal medicine in five, and acupuncture in two. One case tried treatment by traditional Korean exorcism. All these treatments eventually proved to be ineffective.

After the diagnosis of Gilles de la Tourette's syndrome, all patients were treated with haloperidol. The initial dose was usually 0.5–3.0 mg/d, according to age and body weight, gradually increased by 0.5 or 1.5 mg until an effective dose was determined. This was different in each patient, and ranged from 1.0 to 12.5 mg, with a median of 2.5–3.0 mg/d; it did not seem to be significantly correlated with the body weight, age, severity of the symptoms, duration of illness, or age of onset. The period of treatment ranged from three weeks to three years.

With haloperidol, symptoms remitted completely in 21 patients and were partially alleviated in five others, after about one month; this was evaluated by clinical judgement of overall percentage decrease of frequencies of symptoms,

compared with the pre-treatment levels. The average improvement rate was 87%. Combined treatment with diazepam (3–10 mg/d) was helpful in five cases in which emotional tension was an obstacle to treatment. The side-effects of haloperidol were troublesome to many patients: diurnal drowsiness was most common, while acute dyskinesia was the major cause of discontinuing haloperidol.

Twenty-five patients discontinued medication against medical advice, after 3–12 weeks of treatment. In most cases, either the patients or their parents believed that treatment had been sufficient, but 17 patients visited the hospital again after a mean period of 2.6 months because their symptoms recurred; in four of these, the dosage needed to be increased to obtain the same effect as given by previous treatment.

Discussion

In this study, the clinical features of Gilles de la Tourette's syndrome such as age of onset, duration of illness, male predominance, non-significance of birth rank, and relatively high incidence of abnormal developmental problems revealed no differences from those in previous studies on European, American, or Asian patients (Singer, 1963; Morphew & Sim, 1969; Shapiro *et al.*, 1973; Woodrow, 1974; Fernando, 1976; Lieh-Mak, 1979; Nomura & Segawa, 1982; Chen & Lu, 1983; Lees *et al.*, 1984). The frequency of first symptoms, cephalocaudal progression of symptoms, waxing and waning clinical course, frequency of involved muscle groups, and incidence of EEG abnormality were also similar. The seven cases reported by other Korean authors had clinical features almost the same as in this report: the typical syndrome with coprolalia was found in two cases, and multiple motor tics (including vocal) in four. These findings suggest that the clinical history and general symptom pattern of Gilles de la Tourette's syndrome, although rare, are almost uniform throughout the world.

However, there were minor differences: in this study, neurotic traits were not reported as often as in Western series. In particular, obsessive-compulsive personality traits or behaviour problems were less frequent than in the cases reported by Morphew & Sim (1969), Woodrow (1974), and Lees *et al.* (1984). Other Korean authors have reported one case with a history of compulsive behaviour and two cases with obsessive-compulsive personality traits (Rhee & Kim, 1973; Kim & Lee, 1973). However, Shapiro *et al.* (1973) concluded from 34 European and Jewish patients and from the literature that obsessive-compulsive symptoms and traits are infrequent. The lesser incidence of tics or other psychiatric problems in the family histories of this series and of other Korean cases contrasts with the high incidence in Western studies, which had provided a genetic model

for the syndrome (Kidd *et al.*, 1980). There are two possible reasons for this: intentional denial by Korean parents, because of the prejudice against psychiatric illness; and failure to use a standardised rating scale to detect them.

The cause of the syndrome is still obscure. Although there is a trend to believe that it is a neurological disorder of the central nervous system (Shapiro & Shapiro, 1982), supported by the presence of non-specific abnormal EEG findings in half our cases, Korean authors have attempted a psychodynamic formulation. Hostile father figures and inhibited aggression (Kim, 1971; Rhee & Kim, 1973; Kang & Yoon, 1974) have been postulated as core problems; similar findings occurred in some cases of this series. Tics, particularly coprolalia and spitting, might indicate a disturbance in normal balance between a need for tension relief and the capacity to control such actions, suggesting that psychogenic factors may be aetiologically relevant (Ascher, 1948; Dunlap, 1960).

Haloperidol was as effective a drug for Korean patients as it is for Caucasians and other Asians, but the dosage must be individualised; the average improvement of 87% was similar to the rates reported in western countries (Bruun *et al.*, 1976; Woodrow, 1974). Three of the other seven Korean cases were also treated with haloperidol, while another two were treated with perphenazine and chlorpromazine. All these drugs were effective, and their dosage was decreased gradually. However, our study suggests that Korean patients need less haloperidol than Caucasians, who had 6–180 mg/d, frequently in addition to anti-parkinsonian drugs (Shapiro *et al.*, 1973). However, the same authors (Shapiro & Shapiro, 1981) have reported responses to remarkably low doses, e.g. 5 mg daily. Asians may have a genetically different constitutional responsiveness to drugs: Nomura & Segawa (1982) reported that haloperidol (0.75–3 mg/d) was effective for about 70% of 100 Japanese, Korean, and Philippine children with the syndrome, while Chen & Lu (1983) reported that haloperidol (0.5–3 mg/d) showed excellent to fair improvement in eight out of ten patients.

Our findings confirm that the Gilles de la Tourette's syndrome is seen in Korea, and has many features in common with those reported from Western countries. The aetiology probably represents multiple factors, which need to be understood in terms of emotional, behavioural, developmental, hereditary, and organic concepts. Evaluation and treatment should encompass a holistic approach, and include chemotherapy, academic help, counselling, and other psychosocial considerations.

The Life Satisfaction Index - Well-being: Its Internal Reliability and Factorial Composition

The internal consistency and factorial composition of the eight-item Life Satisfaction Index - Well-being, adapted for use with elderly British samples, were examined. Cross-validation was carried out with a randomly drawn community sample of 155 rural people aged 65-89 years. The scale was found to have acceptable internal reliability, but may require modification.

Despite a lack of conceptual clarity, the construct of 'life satisfaction' has attained some popularity among gerontologists, who regard it as a useful indicator of adjustments and successful ageing. It has been observed that life satisfaction is as related to mental health (Liang, 1982). Since depression in later life is relatively difficult to diagnose (Bergmann, 1981), life satisfaction measures may provide a useful indicator of affect and subjective well-being. Gilleard *et al* (1981) reported that the Life Satisfaction Index - Well-being (LSI-W) (Bigot, 1974) was able to distinguish at both admission and discharge between clinically depressed elderly patients and normal volunteer controls.

Of the many life satisfaction scales, only the LSI-W has been standardised for use with a British population. It consists of eight items, derived from the 20-item Life Satisfaction Index - Achievement (LSI-A) (Neugarten *et al*, 1961) by item and factor analysis. There are two four-item sub-scales (Acceptance-contentment and Achievement-fulfilment), which assess respectively current contentment and satisfaction with past achievement. The sub-scales sum to provide an overall measure of well-being.

This study reports data on the internal consistency and factorial composition of items composing the LSI-W. These data are needed for several reasons: Bigot's scale was developed on a male non-random sample, not all of whom were 'elderly' as usually defined (they ranged in age from 55-79); and no cross-validations appear to have been carried out. Since our experience is that the LSI-W is quick and easy to administer, and acceptable to elderly sub-

jects, it could be a useful empirical tool. Data on its internal consistency would support this claim.

Method

The LSI-W was administered to 155 elderly people living in a rural community, as part of a study of life stress and depression; the response rate was 85% of a randomly drawn sample (Wilkinson *et al*, 1985). The sample ranged in age from 65 to 89, with a median age of 73; 85 respondents (55%) of the sample were female. Thirty-nine percent were of social class I and II (Registrar-General's classification, Office of Population Censuses and Surveys, 1985); 55% were married, 36% widowed, and 8% were single. Just over one-third lived alone.

The LSI-W was scored on a three-point Likert scale, with subjects responding 'agree', 'disagree' or 'uncertain' to each of the eight items (Table I). For items 1, 3, 4, and 5, agreement was scored 2 and disagreement 0; for items 2, 6, 7, and 8, disagreement was scored 2 and agreement 1. A response of uncertain to any item was scored 1. The maximum attainable score is 16. Analysis was performed using two SPSS-X procedures: 'Reliability' and 'Factor'.

Results

The mean LSI-W score for the sample was 10.99 (s.d. 3.74). The inter-item correlations ranged from 0.03 to 0.43, with a mean of 0.19. Coefficient alpha (Cronbach, 1951) was 0.66, lower than the value of 0.80 reported by Bigot (which tended to suggest a level of item redundancy). The item-total correlations were all above 0.20, with the exception of that for item 7, which was 0.14; its exclusion from the scale increases coefficient alpha from 0.66 to 0.69. Item 6 also performed poorly, correlating significantly with items 1, 2, and 9 only.

TABLE I
Principal components matrix for LSI-W with varimax rotation

Item no.	Scale ¹	Item	Factor 1	Factor 2	Communality (η^2)
1.	AC	I am as happy as when I was younger	0.816	-0.011	0.666
2.	AC	My life could be happier than it is now	0.687	0.138	0.491
3.	AC	These are the best years of my life	0.604	-0.079	0.371
4.	AC	The things I do are as interesting to me as they ever were	0.578	0.238	0.391
5.	AF	I would not change my past life if I could	0.176	0.648	0.451
6.	AF	Compared with other people of my age, I've made a lot of foolish decisions in my life	0.332	0.186	0.145
7.	AF	When I think back on my life, I didn't get most of the important things I wanted	-0.097	0.739	0.557
8.	AF	Compared with other people, I get down in the dumps too often	0.523	0.526	0.549
Eigenvalue			2.524	1.096	3.62
Variance: %			31.55	13.70	45.25

1. AC = Acceptance-contentment, AF = Achievement-fulfilment

Bigot reported a coefficient alpha of 0.7 for the Acceptance-contentment sub-scale and 0.60 for the Achievement-fulfilment sub-scale. In this study, however, the respective values were 0.65 and 0.41. Given the small number of items, the acceptance-contentment sub-scale looks impressive, with the item-total correlations ranging from 0.35 to 0.57 and a mean inter-item correlation of 0.32. In contrast, the mean inter-item correlations for the Achievement-fulfilment sub-scale was 0.16, and two of the item-total correlations (items 6 and 7) were below 0.2. Only one of the six correlations between items 5 to 8 was above 0.2, although four of the six were significant at the 5% level.

A principal components analysis of the LSI-W with a varimax rotation (Kaiser, 1958) gives rise to two factors (using the Kaiser-Guttman criterion whereby only factors having eigenvalues greater than unity are retained). Child (1970) has noted that when the number of variables is below 20, there is a tendency for this method to extract a conservative number of factors. The factors, their loadings, and communalities are shown in Table I.

Factor 1 accounts for 31.6% of the variance, while factor 2 accounts for 13.7%. The low communality for item 6 suggests that the item is unreliable; otherwise, the rotated factor matrix confirms Bigot's sub-scales. Factor 1 loads substantially on the Acceptance-contentment sub-scale, while factor 2 loads specifically on Achievement-fulfilment.

Discussion

Psychometric theory affirms that reliability is a necessary but not sufficient condition for validity. In this study, we have examined the internal consistency

of the LSI-W because in both research and applied settings it appears to be a useful indicator of affect and subjective well-being among the elderly.

According to Nunally (1967), the adequacy of a reliability coefficient depends on the purpose for which the measure is needed. For most purposes, the LSI-W reliability coefficient of 0.66 is perfectly adequate, particularly if this measure is used as part of a battery of questionnaires and tests as suggested by Bigot. Of some concern, however, is the poor performance of item 6, which is not explained by either factor, and we recommend that this item be omitted from the LSI-W. In their analysis of the LSI-A, Wood *et al* (1966) and Adams (1969) recommended that the same item be excluded from that scale. Item 7 also performed poorly in the item reliability checks, and could also be considered for rejection. Chown (1983) stated that "a person's evaluation of his or her life is likely to be influenced by past and present objective situations and by his or her own assessment of them". The LSI-W would appear to be a more adequate measure of current satisfaction than past achievement, and should be scored and interpreted as a single scale, rather than as two sub-scales.

Acknowledgements

The collection of the life stress data was supported by a Mental Health Foundation grant to Professor J. R. M. Copeland, whom the authors would like to thank.

Severe Lactic Acidosis Following Paraldehyde Administration

A case of severe lactic acidosis following paraldehyde administration is described, and the adverse effects of paraldehyde reviewed.

Paraldehyde was introduced into medicine over 100 years ago by Cervello (1884) and Strahan (1885). It has been used in a variety of clinical situations, including the emergency treatment of convulsions associated with tetanus, eclampsia, and status epilepticus, basal narcosis, and obstetric anaesthesia. Its current use is limited to psychiatric units, particularly those without resident medical cover. Despite its widespread use during the past century, little is known about its pharmacology, metabolic fate, or toxicity. Although it has generally been regarded as a particularly safe agent, it has a very low therapeutic index, and large doses produce respiratory depression and hypotension (Goodman & Gilman, 1985). Drug-induced metabolic acidosis has been reported following prolonged use and after overdose (Beier *et al*, 1963). The following case report shows that severe acidosis can also occur after relatively small doses.

Case Report

A 30 year-old male patient was transferred to the psychiatric unit's medical ward in order to review his anticonvulsant therapy. Control of his fits had been difficult in recent months, with one or two *grand mal* seizures occurring every week. Physical examination and initial biochemistry were normal (Table I).

During the following day, the patient had three *grand mal* seizures within 12 hours. Fresh paraldehyde (a total of 40 ml) was administered intramuscularly during this time, since there was neither resident medical cover nor intravenous access to the patient. Six hours after the last fit, the patient was found to be hypotensive (blood pressure

80/40 mmHg) and tachypnoeic (respiratory rate 30 breaths/min). He was drowsy, but rousable. Biochemistry at the time (Table I) showed a severe metabolic acidosis, with an anion gap of +38 (normal range 10–14) and serum lactate of 27 mmol/l. The patient was resuscitated with normal saline and sodium bicarbonate solution, administered intravenously. No more paraldehyde was given. Diazepam was given intravenously to control two further seizures the following day, at which time his biochemistry had returned to its previous values (Table I).

Discussion

There are two main routes for the excretion of paraldehyde: 11–28% is exhaled, and 70–80% metabolised

TABLE I
Serial electrolyte results

	Day 1: mmol/l	Day 2: mmol/l	Day 3: mmol/l
Na ⁺	143	147	140
K ⁺	3.8	3.5	3.8
Bicarbonate	29	9	28
Cl ⁻	106	100	104
Urea	5.8	6.4	6.8
Creatinine	77	110	75
Anion gap	8	38	8
Serum lactate	—	27	1.3

in the liver. It has been suggested that the initial stage is depolymerisation to acetaldehyde, followed by oxidation of acetic acid (Hitchcock & Nelson, 1943), and then via the Krebs cycle to carbon dioxide and water. The acidosis produced by paraldehyde is in excess of that consequent to the oxidation of paraldehyde-derived acetaldehyde.

This may be due to enzyme inhibition during intermediate metabolism (Beier *et al*, 1963). Alternatively, a block in the Krebs cycle could produce a shift in the lactate/pyruvate system in favour of lactate, which could account for the high levels recorded in this case. *Grand mal* seizures themselves may cause a rise in lactate levels, but expected levels would be equivalent to those found in strenuous exercise (5 mmol/l) (Linter & Ryan, 1985). Furthermore, the serum lactate level dropped after the discontinuation of paraldehyde, although there were further *grand mal* seizures.

Previous reports of paraldehyde-induced metabolic acidosis have not provided information about serum lactate levels. In addition to its undesirable metabolic effects, paraldehyde has other drawbacks: it is difficult to store safely and unpleasant to administer (both for nurse and patient).

On exposure to light and air, paraldehyde decomposes to acetaldehyde, which is then oxidised to acetic acid. Several severe poisonings and fatalities

have been reported following the administration of partially decomposed paraldehyde (Agranat & Trubshaw, 1955). Because of this, paraldehyde must be stored in small amber airtight containers, and partially used bottles must be discarded. One study showed that a significant proportion of ward stocks may have decomposed during storage (Goodman & Gilman, 1985).

The administration of paraldehyde is unpleasant; it has a disagreeable smell, and when it is used parenterally a glass syringe is essential, since paraldehyde reacts with some plastics. Deep intramuscular injection to both buttocks is the usual route of administration, and severe, permanent sciatic nerve damage has occasionally followed; more frequently, sterile abscesses and skin sloughing occur at the injection sites. Intravenous administration is particularly hazardous, and may result in hypotension, pulmonary oedema, and venous thrombosis (Goodman & Gilman, 1985).

Thus, paraldehyde in therapeutic doses can cause a marked metabolic acidosis, sterile abscesses, nerve damage, and skin sloughing. The administration of partially decomposed paraldehyde has led to fatalities. We suggest that paraldehyde is an outmoded drug that has no place in today's medicine. Modern benzodiazepines offer a safer, more effective alternative.

Munchausen's Syndrome and Drug Dependence

A man with Munchausen's syndrome was treated for drug dependence, which allowed him to establish and sustain a bond with a hospital, but eventually brought about an ethical dilemma.

Munchausen's syndrome is a rare condition, characterised by patients who repeatedly seek admission to hospital in a state of mental or physical distress, give plausible histories to support their complaints, and submit themselves to painful or even dangerous investigations and therapies, but then abruptly discharge themselves when discovered to have fabricated their stories and physical signs (O'Shea *et al.*, 1984). An association between this syndrome and drug abuse has often been noted (Blackwell, 1968), and Asher (1951) listed the desire to obtain drugs as one of the possible motives underlying the syndrome, although published case reports of patients where a diagnosis of both Munchausen's and drug dependence syndromes have been made are comparatively rare (Hammond, 1980; Mendel, 1974; Bursten, 1965). In reviewing 19 reported cases, Mendel (1974) found that six had a history of drug addiction, but the inclusion of those who had received or demanded large quantities of addictive drugs during hospital stay brought the number to 14. He concluded that these patients should be considered to be suffering primarily from drug abuse, if not addiction, and that treatment should emphasise the drug-dependent nature of the syndrome. Proper labelling would improve the therapeutic relationship.

The generally accepted view is that the craving for drugs reflects a craving for attention and hospital contact (O'Shea *et al.*, 1984; Scott, 1982; Enoch & Trethowan, 1979). Patients may use the diagnosis to gain entry into hospital (Cheng & Hummel, 1978; Hammond, 1980) or as a second line of defence when their fabrications are revealed. Barker (1962) pointed out that these patients do not usually experience withdrawal symptoms when admitted to hospital, although this in itself does not exclude the diagnosis of drug dependence; they may also abscond, despite the offer of maintenance opiate therapy.

We report a case of both Munchausen's and drug dependence syndromes. Although the patient is an unreliable informant, details of his early life, given to different doctors over the years, have been broadly consistent.

Case report

JS is a 42 year-old Scotsman who was born into a large working-class family, the ninth among 11 siblings. The youngest child died of a brain tumour, his father underwent operation for a chronic peptic ulcer on more than one occasion, and his mother had a history of diabetes and cataracts, and died following a cerebrovascular accident.

As a child, JS suffered from chronic otitis media, and required operation for appendicitis at the age of seven. During his late adolescence, he was admitted to hospital for gastroenteritis. He entered the Royal Army Medical Corps at the age of 19, after an unfinished apprenticeship; this introduced him to a medical milieu, where he served as an operating theatre technician, assisting the anaesthetist with intravenous procedures, and handling pain-relieving drugs. At the age of 21, he underwent a medial and lateral meniscectomy on his left knee, following a football injury, and was invalided out of the Army, he has since been largely unemployed.

Shortly after, he began to display the pattern of behaviour typical of Munchausen's syndrome. He would arrive in a casualty department in the early hours of the morning as an acute emergency, and be admitted to a medical or surgical ward. The presenting picture varied over the years: it included acute intestinal obstruction, mastoiditis, renal colic, and less frequently meningitis, cerebral abscess, prolapsed intervertebral disc, and mechanical disorders of the knee. To support the diagnosis, he would sometimes rely on past injuries (e.g. abdominal scars, chronic ear discharge), but would often falsify investigations (e.g. by contaminating urine samples with blood from a pinprick in the thigh). As a result, he underwent at least three exploratory laparotomies, a right and then a left radical mastoidectomy, and also left temporal burr holes following a suspicious brain scan. It is not clear whether he was actively seeking opiates in the early stages, but certainly from the age of 24 onwards, hospital case notes record such suspicions with increasing frequency. He would never remain in any one locality for more than a few months; by then the hospital would have liaised with his previous contacts, and be resistant to further involvement. Indicative of the extent of his travels is a 12-month period between 1968 and 1969, when admissions were recorded in Aberdeen, Blackpool, Manchester, London, and Jersey. He even crossed international boundaries: we have traced records of his contacts with hospitals in Switzerland (in 1977) and France.

His first contact with the psychiatric service was at the age of 16, following an overdose. He was at times referred for psychiatric assessment, but was uncooperative, and defaulted from any treatment offered. At the age of 28 (the year of his mother's death), he presented with quadriplegia; this was soon found to have no organic basis, and so he was referred for psychiatric treatment. Attempts were made to help him to express his difficulties and conflicts in psychological terms, rather than as physical symptoms, but he responded with aggressive behaviour and by absconding; in fact, he gained admission to another hospital with abdominal pain. On his return he took an overdose of aspirin, and later swallowed glass fragments of a light bulb, but without ill-effects. In the same year, the Home Office was first notified of his suspected drugs dependence.

At the age of 31, he accepted treatment at a drug dependence unit for the first time. The nature of his dependence was atypical, in that the drug he most desired was the relatively milder opiate pethidine, and the preferred route of administration intramuscular. He had no contact with illicit sources of supply, and generally received his opiates from

hospitals. It is also noteworthy that there is no record of physical withdrawal symptoms while in hospital under observation, as well as a suspicion that he may have sold some of his prescribed drugs. The only substance he abused was alcohol, and he has convictions for drunk and disorderly behaviour and for assault.

Over recent years, he had become more overtly drug-seeking, demanding greater doses of opiates; any attempt to limit the quantity or manner of prescription resulted in increasingly self-destructive acts. These usually involved cutting and piercing instruments, although he also overdosed, and once set fire to his clothing. He has cut his wrists to the extent of exposing fascia and nerves, and then refused treatment until he had received intramuscular pethidine. Since the age of 32, he had swallowed such objects as razor blades, stitch cutters, and needles on at least ten occasions; this resulted in many operations. Following the first laparotomy and gastrotomy, it was decided to withhold pethidine, but within days, he again swallowed razor blades. In 1985, when a casualty officer refused to supply him with opiates, he stabbed himself in the abdomen, penetrating the small bowel.

These repeated insults resulted in a number of complications. Five years ago, he developed a faecal fistula between the transverse colon and the anterior abdominal wall, requiring a colostomy and closure, which later led to a chronic ulcer and incisional hernia. He had also been treated for partial bowel obstruction due to multiple adhesions, although his recovery was at times suspiciously rapid. His drug dependence led to serious complications: repeated intramuscular injections produced infection, inflammation, and ultimately fibrosis of the muscles in the thigh and buttocks. The resultant limitation of movement means that his knees are fixed and immobile, and when he is seated, his legs stretch out parallel to the floor. In order to walk, the relative immobility of his hips force him to propel himself by swivelling his pelvis in a strutting, waddling gait. He has had numerous hospital admissions for abscesses in the groin and buttocks, and the frequency with which they recur indicate that he may deliberately provoke the sepsis, or at least prevent it healing. Over the past five years he has had 57 separate admissions, of which 12 were to psychiatric wards.

The two drug dependence clinics that have been involved in his care have tried various methods of containing his behaviour, including in-patient detoxification, compulsory detention orders, and daily attendance to collect his prescribed opiates. These failed, as did attempts to convert him from pethidine to the less easily obtainable methadone hydrochloride, and from intramuscular to oral forms of medication. His response to pressure has been to utilise his many physical disabilities to gain admission to other hospitals, and thereby the desired drugs. Failing this, he has restored to acts of self-mutilation.

Throughout, he has remained a loner, and the only relationships he has been able to sustain have been with hospital staff. When frustrated, he quickly becomes querulous, vocal, and threatening, and he can be manipulative with scant regard for the truth. He has served two brief prison sentences for assault and theft, and was recently fined for two shoplifting offences.

Discussion

Many explanations and theories have been advanced regarding Munchausen's syndrome. Enoch & Trethowan (1979) remarked that "in nearly all cases the early environment of these patients is unfavourable, leading in some or other way to their become conditioned, in a sense, to use symptoms as a means for seeking attention". A large family such as this patient possessed may have lacked the resources to satisfy the needs of all its members, and illness behaviour (Mechanic & Volkart, 1961) may then have become a powerful mechanism to evoke and receive the necessary care and attention. Role models were provided by family members, his own childhood illnesses, and his subsequent exposure as a paramedic. Reed (1978) noted the frequency with which symptoms develop soon after an illness which necessitated admission to hospital: in a patient with a personality disorder, admission at a time of social stress may lead to the discovery that hospital care brings short-term relief, whereas discharge leads to re-exposure to the stress of normal social interaction. JS had centred his life on institutions, passing from his family to the Army and then to hospitals, without developing any significant social contacts outside these structures. His encounters with the hospital service had usually been brief, initially evoking interest and concern, and leading to a multitude of investigations and treatments. This initial zeal on the part of hospital staff was replaced by a sense of defeat, with resultant feelings of frustration, anger, and eventual rejection, forcing him to search out new doctors in fresh localities.

By adopting the role of drug dependence, this patient succeeded in establishing a bond with a hospital clinic and sustaining it over a period of years, despite frequent interruptions. Recasting the problem in the mould of a drug dependence syndrome satisfied both this patient's need and the requirement of the health service for an acceptable mode of interaction. But this has, with the passage of time, brought about an ethical dilemma: the continued prescribing of intramuscular pethidine will lead inexorably to greater disability, yet the patient steadfastly refuses to allow any interference or alteration of his drugs. Furthermore, his self-destructiveness has shifted increasingly from a passive to an active form. Rather than a means to communication, drugs have now become an end in themselves, a tangible symbol of the attention he so craves. For this particular patient, the outcome has not met the optimistic expectations of those who have advocated an emphasis on drug dependence in the management of Munchausen's syndrome (Mendel, 1974).

Treatment of Depression in Huntington's Disease with Monoamine Oxidase Inhibitors

Depression is common in Huntington's disease. It is customary to treat such patients with tricyclic antidepressants, although there is disagreement about their effectiveness. The use of monomine oxidase inhibitors for depression in HD has not previously been reported; three cases are described here. MAOIs appear to be of value in the management of depression in HD.

Psychiatric syndromes are among the defining features of Huntington's disease (HD). Huntington (1872) included in his description a "tendency to that insanity that leads to suicide." However, the nature of the psychiatric syndromes is disputed. Koehler & Sass (1984), reviewing mainly German publications, pointed to the preference for diagnoses of schizophrenia-like states or personality alterations. On the other hand, Bolt (1970) and others have pointed to the prominence of affective symptoms such as reactive mood disorders and apathy, while Folstein *et al* (1979) claim that severe depressive disorder is seen in up to 40% of cases.

Treatment methods include the pharmacological, psychological, and social. It has been suggested that HD patients with depression are helped by tricyclic

antidepressants (TCA) (Whittier *et al*, 1962; McHugh & Folstein, 1975; Folstein *et al*, 1979). and Folstein & Folstein (1981) reported that patients with very severe depression, who did not respond to amitriptyline, had been successfully treated with electroconvulsive therapy. Reports on the use of antidepressants, however, are not uniformly enthusiastic. Caine & Shoulson (1983) evaluated 30 patients with HD, of whom 24 had a definable psychiatric disorder; they noted that pharmacotherapy was modestly beneficial in some cases. Six patients received unspecified antidepressants; five of these experienced an improvement in the cardinal somatic features of their disorder, but the drugs had no effect on those ideational components typically associated with a depressed state. Shoulson (1981) evaluated 22

patients with HD over 13–14 months, and reported that depression lessened slightly in seven of ten patients treated with TCA, but that combined depression scores declined insignificantly; pharmacotherapy often caused adverse effects, and functional capacity declined in all patients even where depression seemed improved.

Monoamine oxidase inhibitors (MAOIs) were not discussed in these accounts, but many controlled trials have shown that they do have a place in the treatment of a variety of ill-defined depressive and anxiety states. I report here the use of MAOIs in the treatment of depressive disorder in three patients with HD; all had generalised chorea and a parent with a diagnosis of HD.

Case Reports

A, aged 23, was admitted because of tearfulness, refusal to eat, anxiety, early morning waking, diurnal variation of mood, and suicidal ideation. She had distressing delusions that everything and everyone resembled one of the nursing staff from a previous admission. She had previously failed to respond to clomipramine (150 mg daily), and was therefore started on phenelzine (15 mg t.d.s.). Her symptoms suddenly abated nine days later; she became cheerful and without thoughts of self-harm, while both her family and the staff considered her choreic movements to have improved. After a year's remission, she was readmitted with recurrent symptoms, shortly after reducing her phenelzine from 15 mg t.d.s. to 15 mg b.d. The larger dose was restored, and she again became much happier. She remained so, despite her chorea and moderate cognitive impairment, for a further year, after which therapeutic measures became unsuccessful.

B, aged 47, required five admissions for psychotic depression over four years. At the time of her fifth admission she was mute, sleeping poorly, agitated, and tearful. She had been taking clomipramine (150 mg nocte), which was discontinued and replaced two weeks later by phenelzine (15 mg t.d.s.). Her home facilities were reviewed, and better accommodation sought. For the following two years she remained well and cheerful on phenelzine, and did not require admission.

C, aged 69, was reported by a nearby hospital. She had been depressed for several years. After admission, isocarboxazid (10 mg b.d.) was administered, but produced debatable improvement in mood, and was therefore discontinued. The patient became clearly more depressed, with headaches and pains in hands and legs; the pains in her hands were such that she was unable to wash her clothes. Treatment with isocarboxazid (10 mg b.d.) was reinstituted. After one week she became happier, the pains faded, she was able to do her washing, and her choreic movements lessened.

Discussion

Patients A and B suffered from recurrent depression, but had not responded to a TCA. In this situation, "the psychiatrist is faced with the choice of electroconvulsive therapy or trying one of the newer drugs or an MAOI" (Shaw, 1977). Phenelzine was chosen with some hesitation, as non-endogenicity is the salient feature in predicting response to MAOIs (Brandon, 1982), and our patients would not clearly be so classified.

The sudden clinical response of A, nine days after the administration of phenelzine, and C, seven days after the reintroduction of isocarboxazid, supports the contention that this was due to the MAOI: Tyrer (1982) reported that a sudden and dramatic change in mood and symptoms takes place. Later relapse took place in A when she reduced the dosage of phenelzine, and her mood improved when it was reinstated in full dosage. B's response was probably due to a combination of favourable pharmacological and social measures. Additionally, the three patients' response to drugs was consistent with the observation of Caine *et al* (1978) that HD patients were exquisitely sensitive to rapid changes in administered psychoactive medications.

There is no reason to postulate that MAOIs may reduce chorea via a specific effect on the known biochemical defects in the basal ganglia of HD patients: i.e. a profound reduction in glutamic acid decarboxylase, the enzyme synthesising γ -aminobutyric acid (GABA); GABA depletion; and depletion of choline acetyltransferase, the enzyme synthesising acetylcholine. On the contrary, MAOIs increase cerebral dopamine, and as such could be expected to exacerbate the chorea of HD, which appears to result from relative overactivity of dopamine mechanisms in the brain (Marsden, 1983). Furthermore, the most effective drugs in reducing choreiform movements are catecholamine depleting agents such as reserpine and tetrabenazine, and dopamine receptor antagonists such as the phenothiazines and butyrophenones (Bird & Iversen, 1974). However, in two of our cases, it was interesting that improvement in chorea followed the use of an MAOI, and was presumably a consequence of mental well-being. The confidence-enhancing and energising effect of monoamine oxidase inhibitors may be pertinent, particularly in HD, where depression and demoralisation are frequently noted.

Autocastration and Biblical Delusions in Schizophrenia

A young male castrated himself in response to the biblical passage, Matthew 19:12. Although extremely rare, autocastration usually occurs in men with chronic paranoid schizophrenia, with a long history of delusions of sexual guilt which can only be relieved by castration. Management of these patients is long-term, involving both pharmacotherapy and individual and family therapy.

The act of deliberate self-mutilation of the genitals in men is a rare phenomenon; Greilshiemer & Groves (1979) reported only the fifty-third such case in English. In their review of literature, Greilshiemer & Groves were able to identify three general groupings of genital self-mutilators:

- (a) psychotic men, including younger acutely psychotic men with sexual fears, older men with psychotic depression and serious somatic illnesses, and men prone to violence during pathological intoxication with alcohol
- (b) non-psychotic men; either those with character disorders who act out of rageful feelings against themselves or close objects, or transsexuals who premeditate their own transsexualising surgery
- (c) those influenced by sociocultural factors, including complex religious beliefs regarding their sexual group, and difficulty in the male sex role.

A case of genital mutilation that falls into Greilshiemer's first category of younger acutely

psychotic men with sexual fears is reported here. It is distinguished by the fact that the patient is one of a small group of remarkably similar schizophrenics who have committed autocastration due to religious delusions, based on a literal interpretation of the Bible's comment on celibacy (Matthew 19:12): "There are eunuchs born that way from their mother's womb, there are eunuchs made so by men and there are eunuchs who have made themselves that way for the sake of the Kingdom of Heaven."

Case Report

The patient was born in a Queensland provincial town, of elderly parents. He was one of non-identical twins, and the birth was difficult; the patient's mother described him as a "blue baby". He reached his developmental milestones at the usual ages. His father was a retired grazier, who taught his sons to castrate bulls – the same technique the patient used on himself. His twin brother was described as "totally different", and did not have a psychiatric history.

As a child, he was very quiet and close to his family; he had few friends. His mother described him as her "pet". His early school performance was fair, but he struggled in his senior years, failing Year 12. He worked for a year in the Public Service, but left this job, claiming all the men were homosexuals and smoked too much. He denied any homosexual or heterosexual experience: he had never had a girlfriend, and his only sexual experience was masturbation – the source of his guilt and anxiety. There had been no religious upbringing by the patient's parents, but at the age of 17, he had become greatly influenced by an eccentric elderly aunt, who was described by the patient's parents as a religious fanatic. She introduced him to the Bible, and he was baptised. His interest in the Bible increased, until every spare moment was spent sitting in his room reading the Bible from cover to cover. At the time of admission, the patient held a low-key job as a storeman; he lived at home with his parents. He did not drink, smoke, or take illicit drugs, and his only interests were the Bible and attending church.

In 1985, at the age of 31, he incised his scrotum with a razor blade, severed his testicles, and flushed them down the toilet. He was brought to hospital in hypovolaemic shock, with a haemoglobin level of 7.9 g/dl (normal range 13.0–17.0 g/dl); he was resuscitated and the bleeding points ligated. When surgically stable, he was transferred to the psychiatric unit.

The patient stated that he had castrated himself in response to Matthew 19:12; he felt evil, as he had been masturbating, and castration was the only way to gain forgiveness. He had considered cutting off his right hand, in response to Matthew 18:8, but considered that 19:12 was a specific reference to himself. He admitted to occasionally hearing non-hostile voices describing his actions, but these were not prominent in his illness.

The patient had considered castration for at least five years prior to actually committing the act; at times he had consulted surgeons, requesting this, and had been referred for a psychiatrist's opinion. In 1980, a self-inflicted

laceration to his penis required suturing, and he was subsequently admitted to another psychiatric hospital. A diagnosis of schizophrenia was made, and he was given fluphenazine decanoate injections (12.5 mg monthly). He received out-patient treatment over the next five years. Eight weeks prior to the present admission, he had appeared agitated, and refused his medication.

The patient was in good physical condition, and had no significant medical or surgical problems. There was no family history of psychiatric illness.

When he had been fully resuscitated, mental state examination revealed a vague, perplexed, man; speech was soft and quiet, and he presented a detached, flattened affect. His thought content conveyed his great sense of relief at having finally castrated himself, and at no stage did he request analgesia. His thought form was disordered, with loosening of associations and a marked inter-penetration of bizarre religious themes; there was no evidence of any underlying organic disorder, and all investigations, including EEG and computerised tomography, were normal.

The patient was started on major tranquillisers, with a corresponding rapid settling of his acute symptoms. He became more sociable and outgoing, but continued to be preoccupied with the Bible, and showed no regret for castrating himself. He refused to take replacement testosterone, for fear of getting renewed sexual desires. Because of these persistent religious delusions, simple religious arguments were incorporated into a supportive psychotherapy programme (Kushner, 1967), when his feelings of self-harm and sexual guilt were discussed.

The patient's parents were also interviewed, and found to be bewildered at their son's plight. After six weeks, the patient was discharged home on fluphenazine decanoate (50 mg i.m. fortnightly), and has remained well at subsequent follow-up.

Discussion

A review of the English-language literature on male genital self-mutilation confirms Greilshheimer & Groves' (1979) finding that such cases are extremely uncommon, and reports of cases of autocastration similar to that reported here are especially rare: only two were found.

Blacker & Wong (1963) reported four cases of genital self-mutilation, and from these identified five common elements: a lack of variety of human experience during the patient's formative years – particularly the absence of a competent male to identify with; overcontrolling mothers, who insisted on submissive masochistic responses from their sons; strong pathological feminine identifications, usually denied but apparent during intoxication, dreaming, and psychoses; physical repudiation, first symbolic and then actual, of their genitalia; and guilt, shame, and anxiety, often relieved by the self-mutilating act.

Unfortunately, Blacker & Wong do not offer a diagnosis in any of these cases, and only one case was

of an actual autocastration. Also, the histories of alcoholism, antisocial behaviour, and the absence of religious delusions are significantly different from the case reported here.

More marked similarities are found in the two cases reported by Kushner (1967). A 37 year-old divorced man with a five-year history of schizophrenia and extreme religiosity castrated himself as a means of seeking "purification of the spirit" for sexual guilt. Five years later he amputated his penis, this time citing as his reason Matthew 19:12. The second case was of a 42 year-old man with schizophrenia and bizarre religious delusions, who castrated himself in search of purification, again citing Matthew 19:12. Kushner comments on the extreme preoccupation with the Bible and the development of religious delusions in these two schizophrenic patients; as with the present case, he reported that they were ridden with guilt, especially regarding their sexuality.

Sweeny & Zamecnik (1981) noted that previous self-mutilation was a significant predictor of more such action in schizophrenia: such is the case in these autocastrators. They also report that a change in body appearance often precedes a self-mutilating act in schizophrenic patients: this was seen in one case described by Kushner, where the patient shaved his head prior to autocastration. Unfortunately, such predictors are only too easy to identify with hindsight.

In the management of self-induced genital injuries, Mendez *et al* (1972), as well as others writing in urological journals, stress the importance of preservation or replacement of testicular androgen activity. However, this was not possible in the case reported here, as the patient became quite anxious at the prospect of replacement testosterone rekindling his sexual desires and more guilt feelings. This is not surprising, considering the patient's delusions

and the way in which he disposed of his testicles originally. Greilsheimer & Groves (1979) noted that "those individuals adamantly opposed to surgical repair of the diserved genitals will almost always dispose of the organs at the time of the act; individuals ambivalent about the act may bring their organs with them to hospital." This latter group should be considered for surgical repair.

Management of this patient incorporated a three-phase approach. Firstly, treatment with major tranquillisers produced a lifting of the more acute psychotic features. Secondly, low-key psychotherapy used the patient's religiosity to discuss and, it was hoped, prevent further self-mutilating attempts. Finally, the family were involved to overcome their horror and disgust, and to encourage them to support their son. Further out-patient follow-up will be needed at frequent intervals for many years, due to the high risk of more self-mutilation.

Thus, a small group of schizophrenics who castrate themselves in response to a Biblical passage can be identified. Typically, these men are chronic paranoid schizophrenics whose psychosis attracted medical attention many years prior to autocastration. Following years of obsessive studying of the Bible, they develop a complex delusional system in which they feel the need to castrate themselves in accordance with Matthew 19:12, to atone for perceived sexual guilt. The actual autocastration is not impulsive, but follows careful deliberation by the patient, who has usually presented surgically with a request for castration before taking matters into his own hands. The need to recognise the serious implications of such requests is clear.

A Case of Anorexia Nervosa with Klinefelter's Syndrome

This is the first reported case of anorexia nervosa in association with Klinefelter's syndrome. Although the patient was initially diagnosed as suffering from 'atypical' anorexia nervosa, Klinefelter's syndrome was cytogenetically proven and other organic pathology ruled out.

Case study

The patient, a 20 year-old single male, was referred to the Eating Disorders Unit in March 1985, by the Adult Endocrine Unit of the Johannesburg Hospital. His main complaints were loss of weight over two years, from 50 kg to 39.9 kg, and vomiting five times per week for the previous two months. He denied any fear of becoming obese, excessive exercising, or laxative abuse, but admitted to loss of appetite, drinking excessive amounts of liquids, and persistently feeling cold. He was found to be fatuous, a slow and fussy eater, and untruthful about his food intake.

He had previously been admitted to the Unit in 1978, when he was diagnosed as suffering from typical anorexia nervosa (AN); he was then placed on the Unit's treatment programme, which included individual psychotherapy and a nursing care refeeding plan. He responded slowly, but did not reach the ideal weight for his height and age; after five months he was discharged, mainly because he was uncooperative, and was referred because of delayed puberty to the Paediatric Endocrine Unit. Over the next six years, his weight increased from 31.5 kg to 50 kg, and his height from 154.1 cm to 163.4 cm, so he was still underweight.

At admission, physical examination revealed a cachectic patient with a eunuchoidal body, long arms, and excessively long legs. Axillary hair was absent, and he displayed a female distribution of bodily hair, with sparse pubic hair. His penis size was normal, but his testes very small—5 ml on the left side and 3 ml on the right (normal values 12-15 ml).

He was conceived when his mother was 37 years-old, and was the last-born of three children; the pregnancy was uneventful, but the labour was prolonged, and delivery was assisted with forceps. No psychiatric problems were reported in the family. The patient's father is a successful salesman, happily married to an occupational therapist. His brother is a business executive, and his sister is married and works as a magazine layout designer. All the family members are concerned about the patient—especially his mother, who has gone to great lengths to induce him to eat normally.

It was decided to regard the patient as an 'atypical' anorexic, and to investigate him thoroughly; this was precipitated by his continual loss of weight and vomiting, despite being on the behavioural programme. All routine blood, urine, and stool analyses were normal. Hormone levels, including investigation for Addison's disease, were within acceptable limits. A full gastrointestinal workup revealed no abnormality. Chest X-ray, EEG, X-ray skull and pituitary fossa, as well as three computerised tomography scans and visual field tests, were within normal limits. The only abnormality found was a bone age consistently five years behind his chronological age; as a

result, he was placed on testosterone and chorionic gonadotrophin, both of which were stopped on his present admission. Chromosomal analysis had not previously been carried out, but cytogenetic studies revealed a 47XXY karyotype in all 14 cells examined. The diagnosis of Klinefelter's syndrome was consistent with the physical signs, as well as with the mental status finding of fatuousness.

As a result of these investigations, the patient was regarded as a case of AN whose behaviour was affected by the associated Klinefelter's syndrome. He returned to the behaviour programme, and chlorpromazine was introduced. The vomiting stopped, and he began to gain weight. Unfortunately, the patient then again became more and more difficult and uncooperative. Three months later, he discharged himself from the Unit.

Discussion

Klinefelter's syndrome is a form of male hypogonadism, resulting from non-dysjunction of one of the parental gametes at the time of meiosis; advanced maternal age is known to increase risk of non-dysjunction. The only constant physical feature is small testicular size, but numerous other signs may be present, including congenital defects, neoplasias, endocrine abnormalities, and psychiatric disorders. The patient is usually infertile, fails to develop normal male secondary sex characteristics, and has retarded pubertal development. As the role of puberty may be an important aetiological factor in the development of AN, this feature of Klinefelter's syndrome is quite significant. It has also been highlighted by the tenuous relationship between Turner's syndrome and AN, of which there are 12 reported cases. It is suggested that these individuals have problems with puberty, autonomy, body changes, or body image (Garfinkel & Garner, 1982).

Our patient was psychosexually immature, but had heterosexual fantasies, and did not appear resistant to the development of male secondary sexual characteristics (as seen by his submission to hormone therapy). It has been suggested that significant homosexual conflicts precede AN in up to 50% of male patients, but no evidence of this was found in our patient. His parents are older and from a higher social class than average, but there is no noteworthy family psychopathology (Garfinkel & Garner, 1982).

The patient's anxiety and preoccupation about meals, together with his dishonesty, excessive time spent over every meal, and vomiting indicate a definite weight phobia.

It has been suggested that more serious pathologies exist among male anorexics, since the sociocultural

influence, regarded as an important factor among female patients, is of less significance in male anorexics.

As Klinefelter's syndrome is almost certainly under-diagnosed, it is suggested that atypical cases of male AN be subjected to chromosomal analysis.

Books Reconsidered

*Dementia praecox oder die Gruppe der Schizophrenien: 'Eugen Bleuler**

MANFRED BLEULER AND RUDOLF BLEULER

Eugen Bleuler's motivation for his work with schizophrenic patients and for describing their psychoses in a manual (By Manfred Bleuler)

Bleuler's aim in becoming a doctor and his interest in schizophrenia are deeply rooted in his origins. He was born on 30 April 1857 (his father lived from 1823-1889, his mother from 1829-1898). All his ancestors were from Zollikon, which was, up to the end of the last century, a rural village an hour's walk from the city of Zürich. The population of Zollikon lost some of its ancient rights during the 18th century and had been increasingly subjected to the government of the city of Zürich. Up to 1830, an academic career was unusual and difficult for the rural population; it remained difficult during Bleuler's youth. It is astonishing, however, that in spite of the difficult access to academic education, the intellectual interest and the enthusiasm for the ideals of enlightenment grew even greater among the rural population.

It became increasingly important for the rural people to give an academic education to their young men. The hope grew: if our sons are academically trained they will be able to perform their duties as clergymen, judges, and particularly as doctors as well, or even better, than the old aristocrats of the city. Under these circumstances, Eugen Bleuler decided to become a doctor, and he understood medicine as part of natural sciences.

The first directors of the psychiatric University Clinic Burghölzli in Zürich (opened 1870) were highly qualified and internationally-known professors who became famous on account of their research in neuropathology and in neurophysiology. As Zürich at this time had no academic tradition, they had been called to their chairs from Germany.

The rural population felt that these great men had no personal contact with their psychotic patients on account of their academic interests and their language (the population spoke a German dialect). Under these conditions, Bleuler conceived the overwhelming wish to become a modern doctor who lived and spoke with them in their mother-tongue. He had the wish to become a psychiatrist such as the population around him had dreamed of - a psychiatrist who

could help his patients both by modern medicines and by understanding them personally and being close to them.

Bleuler completed his medical studies in Zürich in 1881. In the following years, he was an assistant in the psychiatric clinics of Waldau-Bern and Burghölzli-Zürich and also studied in Paris (under Charcot), in London, and in Munich (under von Gudden). One of his first publications as a young student concerned synaesthesia (1880). There followed papers on cerebral anatomy, neurology, and neurophysiology.

While an assistant of Auguste Forel in the Burghölzli Clinic, Bleuler was chosen as director at the psychiatric Clinic Rheinau, at the age of 29. He stayed there from 1886 to 1898. Rheinau was at that time a small village of farms. In the 8th century, a monastery had been founded there on an island in the Rhine. In 1867, it had been turned into a psychiatric hospital. Bleuler was not yet married, and lived there alone, in contact with his patients. He worked with them (mostly in agriculture), organised their free time (for instance, hiked with them, played in the theatre with them, and danced with them). He was also the general physician of the patients of the Clinic and the inhabitants of the village. During his life with the patients, Bleuler had always a memo-pad at hand, where he noted what touched and interested him in his patients' behaviour. He frequently noted in shorthand what the patients actually said.

In 1898, the government of the Canton of Zürich appointed Bleuler as Auguste Forel's successor as Director of the Psychiatric Clinic Burghölzli and as Professor of Psychiatry at the University. He did not wish to leave his patients in Rheinau, but in his new position in Burghölzli, he was much closer to his sick parents.

In his new position, Bleuler had less time for his patients, as he had many other duties. He worked in close touch with his staff, which included Carl Gustav Jung from 1900-1910; they discussed (in touch with Sigmund Freud) the psychodynamic life of schizophrenics.

In the first years of our century, a group of German psychiatrists, headed by Gustav Aschaffenburg, Professor in Cologne, planned to write a great *Manual of Psychiatry* (13 large volumes). Its main aim was the exact description of the manifold psychopathological phenomena, and an effort to outline disease entities

*Published by Franz Deuticke Editor (1911) Translation in English (1950) *Dementia Praecox or the Group of Schizophrenias* New York. International Universities Press

with specific cerebral causes. This was intended to be a continuation of what Kraepelin had inaugurated with his textbook.

Aschaffenburg knew Bleuler both on account of his contribution to the introduction of Kraepelin's conceptions and for his great but critical appreciation of Freud's concepts. Bleuler's motivation for writing the *Manual's* volume on *Dementia Praecox* clearly reflected his principal aims in life: he wanted to be a physician in the sense of his time and to contribute to the progress of medicine, and he wanted at the same time to be close to his patients and to know and study them personally. He was eager to describe psychopathology in an objective, scientific way and to suggest at the same time the importance of understanding the personal psychodynamic life of the individual patient.

The main text of the book

It commences with a short presentation of the history of the concept 'dementia praecox'. Bleuler introduced the term 'schizophrenic psychoses' both in order to eliminate the erroneous idea that the patients become 'demented' and to take into consideration that not all patients become psychotic at an early age. His designation also expressed his doubts in regard to the assumption that 'dementia praecox' corresponds to a disease entity. The following main text, under the title 'Symptomatology', describes in an exact and objective way his observations while living with schizophrenic patients in Rheinau. The chapter is subdivided into 'elementary functions' (the dissociated associations and affectivity, the ambivalence) and 'secondary symptoms' (as for instance hallucinations, delusions, morbid attitudes). All these descriptions are mainly based on Bleuler's daily notes while with schizophrenic patients. These notes filled several thousand small pages written in shorthand. This is the first and most important characteristic of the book: *it is mainly based on personal and direct observations.*

The second characteristic of the book consists of *an endeavour to discover the psychological individual background of the psychotic symptoms.* This is not done by theoretical considerations but by noting observations which concern the psychological background. From Bleuler's description of 'symptoms' emanates his empathy for the patient to the reader. To what is such an emanation due? Certainly not by direct calls for empathy! It may be due first to the fact that Bleuler gives well-observed examples of symptoms noted in much more detail than an impersonal description. Bleuler also repeats again and again that the symptoms were observed in a patient whose emotional and intellectual inner life is essentially

intact, but frequently hidden. Thus, we gain the impression that we are in duty bound to accept the schizophrenic as one of us, and as one who merits our help. The same effect is gained from the demonstration that many 'symptoms' are symbols for emotionally laden ideas of the patients, just as the contents of our dreams are often symbols. Bleuler also describes how patients suffer from ambivalence, from contradictory emotions and impulses (due to double-bind in modern jargon). As it is true of everyone's life to overcome ambivalence, the description of the schizophrenic's difficulties suggests the idea: "He is one of us and we can feel with him".

An example: A schizophrenic woman from the Burghölzli Clinic had asked to see Bleuler. When he saw her, he found her mute and in catatonic stiffness. He suddenly noticed, however, a little movement of the patient: for a short while, she touched Bleuler's wedding ring. This movement suggests the interpretation that the patient wanted to express: "I look like a stone, but I am a woman with healthy feelings appreciating marriage". Bleuler never maintained that his impression of his patient's motivation for touching the wedding ring really corresponded to what was going on in her thoughts. The observation, however, qualified his impression as possibly realistic. And it is certain that Bleuler's impression due to objective observation aroused his empathy for a patient 'looking like a stone'—and it evokes the empathy of the book's readers for catatonic patients.

Chapters superseded by modern research

While Bleuler's exact, minute descriptions of his schizophrenic patients (suggesting empathy through objectivity) are still of value and interest in modern times, the following chapters on course and outcome of psychoses and on the families of schizophrenics have lost their importance in the light of new research since 1911.

Bleuler, however, had already shown that the course of schizophrenic psychoses is extremely varied—with one exception: the schizophrenic never becomes 'demented' and never loses his intellectual and emotional life, even if it is often hidden behind his dissociation of thoughts and emotions. Bleuler mentioned that many schizophrenics recover so far that they can live a healthy life outside hospital. He hesitated, however, to speak of absolute, complete recovery. One of the reasons lies in the critical evaluation of the patient's prepsychotic personality. If prepsychotic personality difficulties continued to exist after social recovery, Bleuler asked himself critically: was perhaps the prepsychotic personality disorder already a sign of the oncoming psychosis?

He feared that the designation of complete recovery was uncertain in such a case, and was not permitted by objective, scientific thinking. Furthermore, for many years Bleuler's main duties did not allow him to follow-up the course of many patients after their discharge from hospital, particularly not during his isolation in Rheinau. Compared with his great experience with hospitalised patients, his experience was restricted with patients discharged from hospital.

Theoretical considerations

One of Bleuler's main aims in choosing and following his career was to arrive at an understanding of the schizophrenic symptoms as expressions of an inner psychodynamic life. And one of the main aims of his book was to describe the results of these endeavours, and to introduce them into modern psychiatry. He studied the schizophrenic's inner life essentially in the same way as we study the inner life of neurotics, of healthy men, and of ourselves. He included in this study ideas of Freud, and discussed them with him.

Bleuler was successful in his endeavours to recognise schizophrenic 'symptoms' as reflecting the patient's life experience, his cognition, his emotions, his fears and hopes. His way of analysing the schizophrenic's inner life enabled him – and enables us – to feel with the schizophrenic, to acknowledge him as 'one of us', a man as we are, worthy of the same social and medical care when in stress and difficulty. The great importance of this becomes evident when we realise how strong tendencies in the opposite direction have frequently existed in all cultures and at all times. All too frequently, the schizophrenic was considered to be no longer one of us, to be wracked and ruined for good, to be a demented and degenerated man, or a man possessed by evil spirits or demons. Even in the psychiatry of our century, there has been a strong trend in this direction, declaring that the inner life of the schizophrenic was incomprehensible to the healthy.

While Bleuler understood the schizophrenic symptoms as a direct or symbolic expression of the patient's inner life, he never claimed that his psychological understanding explained the patient's psychosis. In other words: he did not understand why psychologically intelligible parts of the patient's inner life lose control by experience and logic, to a degree which characterises him as a psychotic, as a man who loses his usual social position. Bleuler understood, for instance, that a schizophrenic's ambivalence is essentially of the same nature as ambivalence of the healthy, that it is due to contradictory emotionally laden life experiences, to the double-bind. However, Bleuler did not understand why this ambivalence becomes overwhelming, why

the patient thinks, feels, and acts in many respects as if there were different souls in him, as if he consisted of different personalities, that he becomes 'split' to a psychotic degree.

It was logical in this situation to assume that hidden behind the schizophrenic symptoms, which are psychodynamically intelligible, is concealed a 'primary disorder'. Like most psychiatrists of his time, such as Kraepelin and Sigmund Freud (and many other psychiatrists of our times), Bleuler supposed that the 'primary disorder' was a metabolic or anatomical cerebral disturbance. Bleuler mentions, however, the possibility that anomalies in personal development could be a primary cause of schizophrenic psychoses. Bleuler looked for symptoms of the 'primary disorder' which were independent of the psychodynamic life. He suspected some physical findings to be 'primary' symptoms, but we know today that some of them are of another nature. He believed that the splitting (the dissociation of thoughts, of emotions, of attitudes and of acting) were close to 'primary symptoms', while he understood most of the other symptoms of the psychosis as due to the intrapsychic, psychodynamic life, as being 'secondary'.

The terms 'primary and secondary' symptoms of schizophrenic psychoses are no longer in use, and sound old-fashioned. The essential content of Bleuler's theoretical conception, however, is astonishingly similar to the conception of most modern psychiatrists: they agree with Bleuler that the symptoms of the schizophrenic psychoses can be understood psychodynamically, and they agree with Bleuler that this understanding does not, as yet, answer the great question: why has the schizophrenic lost all consideration for reality and logic in many ways during his fight to harmonise the inner disharmonies (the double bind) of his life experience? Why has he become psychotic in spite of an inner life which we feel to be near our inner life? In this regard too, most modern psychiatrists hypothesise like Bleuler that behind the psychodynamically intelligible morbid symptoms exists a hidden morbid background of the psychosis. They no longer call it, as Bleuler did, 'primary disease', but their description of 'vulnerability' with regard to schizophrenic psychoses or hidden disturbances only visible by 'markers' corresponds closely to Bleuler's conception. As Bleuler did, most modern psychiatrists suppose that this 'primary disease', this 'vulnerability', is due to an abnormal cerebral function – today, in particular, of a neurohumoral origin. As in 1911, however, up to the present time, no specific derangement such as the deepest and specific derangement of schizophrenic psychoses has been discovered.

The chapters on 'Therapy' (By *Rudolf Bleuler*)

Bleuler excluded the superfluous and the questionable, and based therapy on an established effective foundation. Considering the treatment methods at the present time, we may understand his position. But this attitude explains also why Bleuler expressed himself carefully about the dialogue with his patients.

What principles are specified in his book? The symptomatology of the schizophrenic patient is essentially comprehensible. The underlying factors are the therapist's profound empathy, his sufficient knowledge of the patient's personal history and of psychodynamics, as well as his awareness of the fact that healthy, although split off or distorted parts of the personality, persist even in the most disturbed patient. Uncovering psychotherapy, as with the neuroses, helps only in the less severe cases. The therapist practises with his patient mainly reality-testing and impulse-control. Daily routine and living together in the clinic are aspects which should be embedded in a structured environment. Acting-out destructiveness must be prevented, but at the same time *freiraum* and tolerance should be taken into account, more so than would be possible outside the clinic. The vehicles of therapy are dialogue and an active community life.

And what if we had to summarise the bases of treatment in the present day? We would confirm the fact that therapy should be less uncovering and more structured. In our opinion, the following is true: first, the therapist is not just a good, knowing, and commenting partner in a dialogue, but is the person who fulfills the patient's desire for a parent figure and who, in certain areas of the relationship, is omnipotent and able to fuse with him. This means that the therapist expresses clearly what he thinks to be correct or incorrect. He is capable of verbalising the unspoken feelings and thoughts of the patient, and presenting them in a framework which provides security. He makes no secret about his own feelings and associations which arise in the therapy, or about his personal gain. He confirms the experiences communicated to the patient in the dialogue in a well defined framework on the level of action, which in the end result, is more important for the patient. And, step by step, he draws himself out of his parent role, but is available to the patient if necessary for years. Second, understanding is less causal and analytical than purposive and synthetic; abnormal experience is declared as an expression of a healthy, constructive striving, and must be led out of its distorted and threatening state. Third, because anxiety-raising feelings and impulses are not repressed into the uncon-

scious, but instead are split off into other conscious areas of the personality, it is not the task of therapy to let them become conscious, but to (re)integrate them into the whole of the personality. Fourth, disturbed functions should not just be pointed out, but also corrected and actively trained, for example, cognitive and affective control of reality, phantasising and symbolising, organising and weighing of matters, coherent communication, metacommunication of contradictions, etc. Fifth, the healthy resources of the patient and his family are not just an implicit presupposition for therapy; they should be explicitly applied and strengthened.

If we compare this description with Bleuler's basic statements of 1911, we notice that the latter have maintained their validity up to the present time, but have been developed further and made more precise. Concerning the realisation of these principles in the clinic – Bleuler's main field of work – a certain loss is apparent. There was a state of distress concerning personal and financial matters; there were the difficulties of the pre-neuroleptic era, and the extensive relinquishment of private life. However, one cannot avoid seeing that the clinical setting at the time was more a community of life and destiny between patients and nurses than it is today, and in this sense, it came closer to the ideal of the active therapeutic community.

Conclusion

The main text of Bleuler's book consists of a careful and objective description of his observations during long-term living with schizophrenics – a description which demonstrates the direct and symbolic correlation of the schizophrenic's symptoms with his inner, psychodynamic life.

It is furthermore important that he shows again and again that the schizophrenic is never 'demented' in the sense of Bleuler's time; that he preserves in his background the intellectual abilities and emotional life of the healthy. From Bleuler's minute descriptions of what is healthy in the schizophrenic, and of the correlation of his symptoms with an inner life close to our inner life stresses, comes the conception that the schizophrenic patient is not foreign to us, that he is not unintelligible, and that we can develop empathy for him. The schizophrenic patient needs our help, as does any patient.

For the care of the schizophrenic patient, an active therapeutic community is important. It is essential in therapy that nurses, doctors, relatives, and others are in a natural way near the patient, sharing parts of life with him.

Psychiatrists on Popper

Sir: When a philosopher's work becomes as well known as that of Sir Karl Popper, it must be expected that it would be mis-quoted and mis-interpreted on occasions. Popper appears, however, to suffer more than most, often at the hands of psychiatrists. There have been two recent examples of this.

Taylor (*Journal*, July 1986, 149, 37-41) in his fascinating article on 'Hysteria, Play-acting and Courage', uses Popper's concepts of worlds I, II and III in support of his argument that hysteria is not a mental state but a product of human culture more akin to play-acting. In Popper's terms (Popper & Eccles, 1981) this is therefore a world III phenomenon: world III being the universe of human artifacts such as novels, plays, and gardens. World III develops when consciousness or the human mind (world II) acts upon the material world (world I) to alter it in a meaningful way. Diagnosis, according to Taylor, is a world I phenomenon. This, I think, can be contested. Diagnosis is a concept and hence belongs either to world II or III. For example, in a disease (diagnosis) carcinoma of the lung, the world I phenomenon which relates to this diagnosis is the cancerous tissue itself, which, in itself, is not the diagnosis. That requires a mind (world I) before it can come into existence as a world III phenomenon. Hence, since all diagnoses/diseases are world III phenomena, the use of Popper's concepts in no way advances Taylor's argument that hysteria is different from other diagnoses, an argument which may nevertheless be correct.

The second example by Mathers (*Bulletin*, May 1986, 103-104) criticizes Popper's theory of science as it applies to psychiatry and, in particular, psycho-analysis. Popper's epistemology is a demonstration of the logical asymmetry between verification and falsification in the proof of theories. Mathers disagrees, preferring to believe in the possibility that falsifiability is not a prerequisite for testability and that theories can be *proven* to be true as well as to be false. In that case any theory which has been as decisively proven to be true as many have been proven false must be produced in evidence for this startling assertion. Of course many theories are held to be true by the scientific community because their falsifiability has been used to test them so frequently that a sort of Popperian truce has been called for the

time being – but always with the possibility that an experiment at sometime in the future might disprove or modify the theory.

Mathers makes a further assumption which is attributed by implication to Popper, that non-science (psycho-analysis) is the equivalent of non-sense. Popper has pointed out that this is not the case. Indeed it would be difficult to devise an experiment to falsify Popper's own epistemological theory, but I doubt if he would accept that it is nonsense. Hence, Popper would not necessarily be led into asserting that analysis is non-sense only that it is non-science. Dr Mathers has therefore inadvertently performed for analysis more of a disservice than did Popper.

Tardive Dyskinesia and Parkinsonism

Sir: We read with interest the letter by Drs Oyeboade & McClelland (*Journal*, July 1986, 149, 122-123). Their results coincide with our clinical observations that coexistence of drug-induced parkinsonism (PS) and tardive dyskinesia (TD) in the same subjects is not exceptional, and that the intensity of the two disorders is not correlated. Nevertheless, we do not think that 'an independence of their relative severities calls into question the currently held view that PS results from a blockade and TD a hypersensitivity of dopamine receptors'. Nor do we consider that 'the two conditions are either mediated through different dopamine systems or through independent but related neurotransmitter systems'.

Easier explanations are available. Some nigro-striatal dopaminergic regions could be hypofunctioning as a result of the neuroleptic blockade of these neurons, while other regions could have become 'hypersensitized' after a prolonged blockade at the same time. Differing levels of receptor sensitivity in the corpus striatum have been proposed by Carlsson (1970). Moreover, observations of parkinsonian tremor shifting into a dyskinetic movement would support the hypothesis that dopaminergic hyperfunction, clinically TD, would develop after

hypofunction produced by dopaminergic blockers, clinically PS (Goetz *et al*, 1982). A decrease of striatal dopaminergic neurotransmission by neuroleptics increases sensitivity for the posterior appearance of TD determining the later localization since it affects the same substrate and implies a topographical correlation of both disorders (Garcia Ribera *et al*, 1985). Crane (1972) showed that 'tardive dyskinesia is more likely to develop in patients with pseudo-Parkinsonian symptoms than in patients not exhibiting such manifestations'.

In similar cases, such as L-dopa induced dyskinesias in patients suffering from idiopathic Parkinson's disease, the severity of both disorders is frequently not related without calling into question the coexistence of dopaminergic hyperfunction and hypofunction. In spite of the apparently opposite theoretical support, coexistence of both disorders could be the expression of two different moments in the same physiopathological process. Prospective studies are needed to clarify how and where both drug-induced disorders appear, disappear or shift.

Psychotherapy and Placebo

Sir: Professor Eysenck (*Journal*, May 1986, **148**, 610) says that I failed completely to understand his point. I feel that, on the contrary, it is he who has not understood mine.

I share Professor Eysenck's scepticism as to the 'specificity' of the various types of analytic psychotherapy. I have long thought that any positive or negative effects of the various types of psychotherapy have more to do with the 'non-specific' personal relationship between therapist and patient than with 'specific' factors inherent in the particular therapeutic technique employed — Professor Frank's

'shared therapeutic functions' in fact. That such factors are, to some extent, also operative in behavioural as well as analytic psychotherapy was suggested by the study of Sloane *et al* to which I referred. However, if it is the case, as Professor Eysenck states, that comparative studies show a clear superiority for behaviour therapy over placebos in general and the other psychotherapies in particular, then this is, of course, an important finding, which I never questioned.

The actual words of Professor Eysenck to which I referred and to which I objected were — 'Do we have the right to... get the State to pay us for treatment that is no better than a placebo?' My objections to this were threefold. Firstly, I wished to draw attention to the confusion that can occur in psychotherapy research because both the 'specific' treatment in question (psychotherapy) and the 'non-specific' placebo with which it is compared are both presumed to be psychological in their mode of action. Attention to the conceptual confusion surrounding the terms 'specific' and 'non-specific' in placebo theory has recently been drawn by Professor Grunbaum. His article supports my contention that the allotment of the various therapeutic factors to the categories 'specific' and 'non-specific' (or in his preferred terminology 'characteristic' and 'incidental') is purely arbitrary and relative to the theoretical standpoint of the investigator concerned. Unless we are clear about this Eysenck's statement that 'psychotherapy is no better than a placebo' could be reduced to the vacuous proposition 'psychotherapy is no better than psychotherapy.' I objected secondly because a great deal of psychotherapy is in fact done with little extra cost to the State, and thirdly because the phrase 'no better than a placebo' appears derogatory — especially insofar as people tend to associate placebos with inert pills. In his letter he says that 'placebo treatment is as successful as psychoanalysis and psychotherapy in general...' This at least implies acceptance of the fact that general psychotherapy does have some degree of success even if this is not quantitatively greater than that of placebos in general. Furthermore, the fact that the effects of psychotherapy may not be *quantitatively* greater than those of placebos in general does not, of course, imply that they are *qualitatively* identical. Few, for example, would exchange a therapeutic relationship (whether in a personal or a professional setting) for an inert pill even though both could be regarded as placebos insofar as they are 'non-specific' and psychological in their effects.

The Prevalence of Mental Illness Among People with Mental Handicaps

Sir: A recent publication of the Royal College of Psychiatrists (Wilkinson & Freeman, 1986) contains the following statements:

"Nearly one half of mentally handicapped children and adults suffer from associated psychiatric disorder. Among mental handicap hospital populations, the prevalence is between 30% and 60%" (p. 117).

"Several surveys indicate the prevalence of severe mental illness (psychosis) in mentally handicapped people is between 11% and 13% of hospital residents" (p. 122).

The discussion which followed suggested a weight of opinion in favour of the first quotation.

Two years ago I summarised all the evidence I could find (over a dozen studies) on the subject (Ineichen, 1984). Most of those which gave a figure based on diagnosed mental illness, rather than vaguer measures such as 'disordered behaviour' clustered around the 10 to 14% mark. The highest figure of all was 58.8%, including only 15.8% severe cases which warranted 'continuous and perhaps intensive in-patient care from psychiatrists' while the rest require 'at the most occasional psychiatric specialist attention' (Williams, 1971), the figure of 'up to 60%' has been in circulation for a decade or more. I am still waiting to find a single study which justifies its use.

Violent Behaviour in Psychiatric Hospitals

Sir: I read with interest the paper by Pearson *et al* (*Journal*, August 1986, 149, 232-235) and felt that the

report of the high incidence of violent acts at mealtimes was worth further discussion. Phillips & Nasr (1983) noted a peak of violent incidents resulting in seclusion or restraint between noon and 2.00 p.m. and in a study of my own, incidents resulting in seclusion were about twice as common at mealtimes than at any other time. There was a tendency for non-psychotic rather than psychotic patients to be involved in such incidents, but the type of incidents were no different from those occurring at other times.

Kinzel (1970) suggests that schizophrenic patients are prone to disturbed behaviour at times when they perceive their "body-buffer zone" being encroached upon, particularly if from behind, and Bigelow (1972) states that "the crowding of strangers, especially near such valued resources as food" may result in aggression.

I believe that study of the facilities used in psychiatric units for the serving and eating of food by patients may allow modifications to be made, so reducing the incidence of violence.

Schizophrenia and Ethnicity

Sir: One of the most intriguing facts to emerge from the World Health Organization's International Pilot Study on Schizophrenia (World Health Organization, 1974) is that two-year outcome was the higher percentage of good outcome schizophrenics in Third World countries as opposed to First World countries.

The CATEGO Class S Schizophrenia Study (*Journal*, December 1985, 147, 683-687) is presently being analysed regarding outcome at two years. Preliminary findings indicate that the Xhosa schizophrenics in the sample have a better outcome at two years than the White schizophrenics, but the reason for this is not known at this stage. However, there are distinct differences in terms of cultural factors, attitudes to mental illness, compliance with maintenance medication, expressed emotion and living in extended families, which are of great importance in

transcultural psychiatry. These are facts which have a bearing on the nature and management of the disease and it is to be deplored that Drs Sashidharan and Lipsedge have politicised this information in their recent letter (*Journal*, April 1986, 148, 484).

Scientific truth is a bastion of strength in a world which is confused by misinterpretative and exploitative statements. It is particularly distressing in this regard that Drs Sashidharan and Lipsedge have cast aspersions on the scientific integrity of the *Journal's* Editor and assessors by stating that an article "with politically loaded definitions of little scientific import" was published.

Depression in Schizophrenia: Prevalence and Treatment

Sir: With regard to the paper by Elk *et al* (*Journal*, August 1986, 149, 228-229) although the point has been made previously elsewhere it seemingly needs to be made again.

The "Population Registration Act, 1950 (as

amended)" does not define homogeneous "ethnic groups" but groups together "whites, blacks and coloureds" whose members may have very different origins, languages, cultures and social circumstance from co-members of the same so-called groups. By accepting this paper in its published form I feel that the *Journal* has been done a disservice and that another layer of veneer has been placed on the pseudo-scientific basis of apartheid.

Control of Auditory Hallucinations with Earplugs

Sir: I read with interest Dr Birchwoods article (*Journal*, July 1986, 149, 104-107). I can recall very clearly two schizophrenic patients who wore earplugs to shut out the 'voices'. The first one was a male in his forties that I saw at Castle Peak Hospital in Hong Kong in 1970 and the second was a male patient in his sixties at Springfield Hospital in London in 1977. As I recall, the first patient wore earplugs in both ears while the second only in his left. Both of them told me that the earplug helped to block out the voices. At that time I said to myself "this is just part of their thought disorder" and paid no further attention to it. Another lesson that we should listen more to what our patients say.

A HUNDRED YEARS AGO

A Lunatic Imprisoned Again

Why do the City Fathers persist in imprisoning Herbert Percy Freund, seeing that he is certainly "a person of unsound mind"? Is it that they deem it less costly to keep him one-third of his time in gaol than to maintain him altogether in an asylum? The question of humanity ought to have some little weight as against the question of economy. Besides which, it may one day happen that this lunatic will no longer

be contented with declaiming against St Paul's Cathedral as "that house of idols over there". He may turn iconoclast on his own account; or, instead of predicting the downfall of the City, he may do something towards the fulfilment of his prophecies. The policy of the City magistrates is neither sound nor safe, and it is certainly anything but benevolent.

Book Reviews

Mental Health Law (2nd edition). By BRENDA HOGGETT. London: Sweet & Maxwell. 1984. Pp 370. £12.95.

Mental Health Act Manual. Edited by RICHARD M. JONES. London: Sweet & Maxwell. 1985. Pp 318. £16.75.

Mental Health Services—Law and Practice. By LARRY GOSTIN. London: Shaw & Sons. 1986. Catalogued pages. £85.00.

The Mental Health Act 1983 (England and Wales) is a complex document, like all Statutes, and it is often difficult to follow or is capable of a variety of different interpretations. In comparison with its predecessor there is now an increased emphasis on the rights of mentally disordered patients, greater responsibilities for the social worker, entirely new sections about consent to treatment and the establishment of a Mental Health Act Commission and a Code of Practice which is still very much in the early phase of creation. Inevitably the Act has stimulated the production of a number of new books providing guidance and interpretation and these are three excellent examples.

Each provides a different perspective, and complements the other two. The first is a helpful text; the others works of reference.

Professor Hoggett's book is unquestionably the most readable of the three. The first edition, entitled simply *Mental Health*, was I believe, unknown to most psychiatrists as her (legal) publishers neglected to publicise it to doctors and that was a great pity. The second edition confirms Professor Hoggett as a leading authority in the field of mental health law and it is highly recommended. It deals broadly with all legislation which affects the mentally ill, discusses policies underlying it, the way it is used, interpretation and weaknesses. The material is very well presented, interesting, well-referenced and indexed and the book is reasonably priced.

All three authors are lawyers. Professor Brenda Hoggett is a Law Commissioner. Richard Jones (described as editor but apparently author) is a social worker, solicitor and senior lecturer in social administration at Cardiff. He is also a Mental Health Act Commissioner. His book consists of detailed 'annotations' of each section of the Act (each of which is reproduced) so that the result is rather like

reading a book consisting entirely of footnotes. Most of the comments are supported by reference to authorities such as decided cases, other legislation, memoranda or other authority. Some are the author's own opinions. It is primarily a lawyers manual but would also find its place as an important reference book for specialists in mental health law from any profession, but it is not a book for the student or for those who only require general guidance. But it usefully also collates details of all the forms used in applying the Act, the Regulations, Court of Protection Rules and relevant DHSS circulars.

Larry Gostin is also a lawyer, well known in this country as Legal Director of MIND during the passage of the Act and now Senior Fellow in Health Law at Harvard. He has produced a veritable *magnum opus* which replaces Shaw's *Mental Health Services*, a long out-of-date and much smaller publication. This text is published for the first time in loose-leaf format with the intention that it can be regularly up-dated with supplements provided by the publishers as the law changes. It consists of eight major parts dealing with the structure of the Mental Health Services, personnel (managers, doctors, nurses, social workers, relatives—their roles and functions), admissions to hospital (civil and criminal), the interface between the criminal law and the mental health services, discharge and guardianship, the therapeutic relationship, patients' rights and criminal offences. All of these topics are discussed fully and indeed objectively, with detailed references to case law and literature. Virtually all the relevant statutes, (e.g. the whole of the Mental Health Act 1983), regulations, schedules and circulars are reproduced in full. It is a remarkable achievement and a valuable work of reference but it is not bedside reading. The pages are not numbered and it is difficult to find one's way around; the value of the book would be enhanced by an index. It resembles Gray's *Anatomy* or *Archbold* in size and the publishers might usefully consider a more manageable format if this book is to reach mental health professionals (or even families and patients themselves as the preface hopes) as well as lawyers. It deserves to do so although it is most likely to find its place in the library or on the desk of the enthusiastic specialist.

ROBERT BLUGLASS, *Professor of Forensic Psychiatry, University of Birmingham*

Contemporary Issues in Schizophrenia. Edited by ALAN KERR and PHILIP SNAITH. London: Gaskell (Royal College of Psychiatrists) 1986. Pp 483. £17.50.

This handsomely produced volume is intended as an update of the first special publication of the *British Journal of Psychiatry* in 1967. That was a much more modest affair with the text of ten lectures on schizophrenia sponsored by the RMPA. This time the editors have assembled 29 papers and three 'discussions' on schizophrenia which appeared in this *Journal* between 1975 and 1984. They tell us that "many interesting scientific papers have not been included, preference being given to papers presenting broad reviews". The papers have been edited by the omission of tabulated data and, surely a mistake, of summaries.

The book contains seven sections. The first, on general and historical concepts, includes Kendell's influential 1975 paper on the concept of disease. Six other papers are reprinted, among them one by Szasz with a convincing riposte by Roth. In the second section, on classification and phenomenology, there are two papers on first rank symptoms (by Koehler and Mellor) as well as papers on the US:UK project, DSM-III and other nosological topics. Organic aspects, in the third section, are covered by five papers. Topics include the role of dopamine as well as the viral hypothesis, but there is no paper on CT-scanning. Genetic aspects are covered in four papers in the next section. The editors have been able to find only two suitable papers from the *Journal* for the fifth section on social aspects. One is a speculative piece but the other is a follow-up study by the Northwick Park group of schizophrenics discharged from Shenley. Section six deals with treatment and the three reprinted papers deal only with drug treatment. Finally there is a section on outcome.

The editors' problem is now clear. It is not possible adequately to illustrate contemporary issues in schizophrenia by reprinting 'broad reviews' from any single English language journal. For example, the 1982 volume of *Psychological Medicine* contained reviews by Marsden on motor disorders in schizophrenia and by Stevens on the neuropathology of schizophrenia. Neither topic is represented in the present volume. American and Scandinavian journals during 1975-1984 also often published important papers on schizophrenia, particularly on pharmacology and on community care.

The editors' answer to this problem was to commission 15 new papers. They asked eight "researchers, prominent in a particular field, to provide a new review of their field of interest" and seven "dis-

tinguished psychiatrists to present a series of overviews of the present status of knowledge".

Contributions from the researchers are presumably intended to be surveys of the recent literature and there are eight of them. Topics include cognitive impairment, genetic counselling, expressed emotion, chronic schizophrenia in the community, token economies (in 1986!), rehabilitation, and depressive symptoms in schizophrenia. The seven overviews deal with historical aspects, nosology, organic, genetic and social aspects, pharmacological treatment and outcome. Most of these 15 contributions are up to date, readable, brief yet comprehensive. They occupy 144 pages of text and might have made a useful successor to that earlier publication. Alternatively the editors might have made a collection of the most important papers on schizophrenia in English in the last ten years. The present book is an unsatisfactory compromise.

J. L. GIBBONS, *Professor of Psychiatry, University of Southampton*

Psychotherapy of the Combat Veteran. Edited by HARVEY J. SCHWARTZ. Lancaster: MTP Press. 1984. Pp 315. £22.50.

The main subject of this book is the Vietnam Veteran (VV) and the main therapies are psychodynamic. Combat neuroses in World Wars 1 and 2, the survivor syndrome and the post-traumatic stress syndrome are briefly discussed, principally to illustrate the differences between the long-term emotional problems of the VVs and of combatants in other wars. After a summary, by the editor, of the psychoanalytic approach, with an illustrative case history, there are chapters on the history of the concept of war neurosis; psychoanalytic psychotherapy and the VV; unconscious guilt; transference, counter-transference and the VV; nightmares; brief psychotherapy; and group psychotherapy. Schwartz then writes about the 'Fear of the Dead'; and there two 'cuckoo-in-the-nest' chapters, one on treatment with a drug (a monoamine oxidase inhibitor) and another on the Israeli experience in six wars since 1948.

The clinical features of combat trauma, described by most contributors, include the overwhelming nature of the trauma, producing 'severe damage to the ego' and regression to a primitive level of functioning. Schwartz especially, emphasises the importance of unconscious guilt and the difficulties during treatment (for therapist and patient) because of regression to these infantile levels. Typical symptoms are recurrent, repetitive nightmares; memory flashbacks to the traumatic events; anxiety, irritation,

depression and panic attacks; aggressive outbursts; and somatic symptoms. The VVs have problems with alcohol and other drugs and in their marriages and relationships at work. They often commit suicide, sometimes murder and frequently end up in prison.

These are the general features of the combat neuroses. An additional crucial problem for the VVs is that they are not accepted by their family and the local community when they come home. Neither their actual mothers nor Mother-America welcome them home as heroes. And their images of masculinity, often personified in John Wayne or John F. Kennedy, cannot be fulfilled.

I can only draw attention to a few details. Schwartz highlights the contrast between the apparent lack of conscious guilt, whereby there are no regrets for cruel actions performed and humanitarian acts left undone, and persisting unconscious guilt. In the chapter on brief psychotherapy McKinnon writes about 'dulled forgetting' and 'intrusive remembering' and the importance of changing this 'dysbalance' between remembering and forgetting. Parson describes a multi-group approach, using three different types of groups for three stages of treatment. The first group is supportive and fairly superficial; next comes an insight group and, finally, a recovery group in which wives, sisters, widows and other VVs participate, in preparation for life in the world outside. All the authors describe differences in treatment techniques for the VVs compared with those used for other combatants and with dynamic psychotherapy in general. The focus is on the actual trauma and its relationship to present difficulties rather than on the patient's early life. The authors advise against early interpretations because of the danger of too rapid regression; they emphasise the need for and the difficulties in holding these men. Another problem is the concreteness of the VVs memories: these men cannot develop metaphors and symbols to deal with their terrifying experiences; events which took place ten years before seem to be actually occurring today.

Although these features are present with other very disturbed patients what does seem to be different is the non-acceptance of the VVs by their families and communities. Schwartz, in his chapter on the 'Fear of the Dead' proposes a ritual home-coming welcome—a cleansing and guilt-reducing ceremony—to exorcise the horrors.

I found this book both boring and interesting. Boring because of repetition and overlap amongst the various authors; and because psychoanalytic terms are used extensively, which will make it difficult to read for many and a complete turn-off for some. But the book is interesting because it faces the

contrast between conscious and unconscious mechanisms, because it gives practical descriptions of therapy, and because it not only includes failures as well as improvements but also highlights difficulties for the therapist. It has the usual characteristics of a multi-author volume, the standard of content, style and rigour of approach vary but on the whole I found it well-written. Schwartz in particular writes vividly (in spite of split infinitives) and some of his phrases—'fantasy of attack by the vengeful dead', for example—linger. The many clinical illustrations are useful; the authors are self-critical although, I suppose inevitably, there are no controls nor independent assessments of results. References are apposite and the index is accurate and sensible. The book should be read, although not necessarily bought, by anyone interested in the combat neuroses; it will also interest therapists who look after very disturbed patients.

At least until now, little has been written about therapy of any sort for the VVs. But two books on the subject were reviewed recently in this *Journal* (1986, 148, 354–355). The VVs were also the subject of two American television programmes—*Lou Grant* and *Hill Street Blues*—in the spring of 1986. It looks as if the problems of the Vietnam Veterans will no longer be ignored.

RUTH PORTER, *Consultant Psychotherapist,
Hammersmith Hospital, London*

Behavioral Epidemiology and Disease Prevention.

Edited by ROBERT M. KAPLAN and MICHAEL H. CRIQUI. New York: Plenum. 1985. Pp 450. US\$69.50.

Epidemiologists have long studied the functioning of health care systems and their impact on the health of populations, but more recently attention has been increasingly focused on the relationship between individual behaviour and disease. As interest in behavioural epidemiology has developed the diversity of background of the various investigators has become increasingly exposed. This is particularly apparent cross-nationally and may account for the relative paucity of data.

In this useful book, Kaplan and Criqui bring together contributions from many of the relevant fields in various NATO countries to provide an international and inter-disciplinary perspective. The book is divided into four sections: Methods in Epidemiology; Epidemiology; Stress; Behavioural Interventions.

Selected methodologic issues in the interface between epidemiology and behavioural science are

reviewed in the first section, the first paper providing an overview of current epidemiological research methods. Response bias in surveys is reviewed while Kaplan describes general health outcome measures and the inter-relationship between epidemiology and policy science.

A wide ranging series of papers providing epidemiological evidence that behaviour is related to the development of chronic diseases is presented in the second section. Some of the evidence, such as Burkitt's work on the importance of high fibre in diet, is familiar but other studies investigating dietary components in heart disease, the conflicting evidence on alcohol and mortality, the possible effect of diet on cancer risk, and the benefits of the control of diabetes are less so and provide thought-provoking additions to the literature.

The third section on stress moves into an area of considerable speculation. Evidence is accumulating from a number of countries that the development and duration of illness is related to mechanisms for coping with stress, and that good social networks can buffer its effect. The problem of measuring life stress and social support is difficult, particularly cross-nationally. This is an exciting field and the papers in this section provide insights into the inter-relationship between psycho-social processes and disease.

The final section of this book focuses on the adequacy of behavioural methods for the prevention and treatment of chronic disease, and behavioural interventions in the light of their expected effectiveness are reviewed.

Although it would have been valuable to have had further contributions on methodology, particularly other important sources of bias such as selection, this book provides a welcome addition to recent literature on epidemiology and behavioural interventions by attempting to integrate these areas from an international perspective.

ELIZABETH WATSON, *Research Fellow, Department of Clinical Epidemiology, The London Hospital*

Child Abuse and Neglect: What Happens Eventually?

By KIM OATES. New York: Brunner/Mazel. 1986. Pp 209. \$25.00.

Child psychiatrists are increasingly involved in the assessment and management of abused children and families and, alongside social workers, health visitors and paediatricians, contribute in an important way to child care planning in the courts. Assessing the long-term risks when an abused child remains with its natural family, the adequacy of past or future

interventions, and the likely effects of separations or rehabilitation is extremely difficult as each child, family and support network together form an individual irreversible experiment and the stakes are painfully high. We are dependent on sound research to guide us and unfortunately because of the overwhelming problems this research entails, the literature, while substantial, does not give us many of the answers we need.

Kim Oates, who is Professor of Paediatrics in Sydney, has provided a major contribution to the field, particularly as he covers in a comparative way, both physically abused children and those who have failed to thrive. In this book he describes two prospective studies comparing these groups of children with carefully matched controls. The first half of the book consists of a thorough review of the literature with suitable emphasis on the rather neglected problem of growth failure and emotional deprivation. Perhaps because growth failure is so easily reversed by hospital admission and many of the children catch up physically later on, they are mainly managed by paediatricians. However, the study confirms that these children remain emotionally and intellectually handicapped in adolescence compared with controls from similar social backgrounds. The study also demonstrates that the families of physically abused children show more adverse psychosocial characteristics than those of the nonorganic failure to thrive group which may lead to greater psychological or community interventions with this group. However, one of the main gaps in this otherwise thorough book is the paucity of detail about interventions with all the families. It seems that almost all the children were with their natural parents at the time of follow-up, but it is unclear how often their management involved court appearances, hospital admissions, foster care or other separations between presentation and follow up, which may have affected the outcome. Provision of community child care by the equivalent of social workers and health visitors does seem less developed in Australia than in Britain where such professionals come under close scrutiny whenever there is a disaster. It would be invaluable to know whether a similar prospective study here would produce similar results. Meanwhile, this book highlights the long term emotional and cognitive handicaps suffered by children who have been abused and neglected and emphasises the need for a continued child centred approach even when there is no longer concern for the child's physical health and safety.

A. HALL, *Consultant Psychiatrist, Emanuel Miller Centre for Families and Children, London*

Health, Race and Ethnicity. Edited by THOMAS RATHWELL and DAVID PHILLIPS. London: Croom Helm. 1986. Pp. 278. £17.95.

This collection of papers centres around the contributions of contemporary medical geography which has moved from biological and spatial concerns to a more sociological position. Useful introductions restate the value of *race* as a sociological term, and point out that population genetics has little role in determining variations in health status: a valid point, but it means that the politics of recent intervention in thalassaemia and Tay-Sachs go unexamined here.

Most of the papers concentrate on literature reviews, and statistics proliferate at the cost of concentration on specific issues such as the rickets debate. There are no contributions by psychologists, psychiatrists or anthropologists and, with one notable exception by Jenny Donovan, there is little on the client's expectations and perceptions. Despite the anti-racist perspective, the general approach is positivist with a rather free and unexamined use of such notions as 'stress', 'support' and 'oppression' without suggesting how these work out at the level of the individual patient or in the subdominant groups' self-identity, behaviour and resistance.

Only one paper is specifically concerned with mental health. John Giggs gives a helpful account of the demographic, statistical and diagnostic difficulties in accurately determining the rates of schizophrenia in minority groups. Using the Nottingham Psychiatric Case Register he replicates previous studies of high rates of schizophrenia in minorities but finds that these rates vary with the particular socio-economic area of the city more than is the case for the white British-born population.

The book is regrettably cheaply produced on the now nearly ubiquitous word processor and includes numerous typing errors. However, there is much important advice and warning here for administrators, community physicians and psychiatrists, particularly on the ethics of research with minority groups. As numerous contributors point out, most work conducted in this area highlights the exotic and cultural aspects, selects out minorities themselves as special 'problems', and totally ignores questions of the accessibility and acceptability of health services or the influence of economic factors. These statistical analyses of minority health have nearly always ignored essential, nosocomial factors.

ROLAND LITTLEWOOD, *Senior Lecturer in Psychiatry, Birmingham University*

Medical Applications of the Behavioural Sciences. Edited by JONATHAN J. BRAUNSTEIN and RICHARD P. TOISTER. London: Year Book Medical. 1983. Pp. 528. £24.75.

This large volume serves as an introduction to, what the editors call, "the art of medicine". Their argument is the well-established one that full consideration should be given to the biological, psychological, social and cultural factors affecting the patient's presentation when making a diagnosis or formulating treatment plans. Unfortunately, like

so many texts on "whole person" medicine, this book fails to demonstrate how these factors might be worked with in practice. Each of the twenty four chapters is a discrete entity in its own right and, in the absence of editorial commentaries, the onus is on the reader to achieve a synthesis of the diverse concepts presented and to consider their clinical implications.

The text is divided into five sections, the themes of which are biology and behaviour, psychological factors, social and cultural influences, the life cycle and doctor/patient issues. In their endeavour to provide a comprehensive review of the field, the editors have included everything from neural transmitters to ethnic influences on symptom formation. Laudable though such an ambitious project might be, a consequence is that relatively little space is devoted to such well-researched areas as chronic pain and biofeedback, while the developmental and social chapters contain much that is speculative. It is a matter of opinion as to whether the achievement of balance is more important than an accurate reflection of the state of scientific knowledge in each of the areas covered.

Like so many introductory text books, the majority of authors fail to acknowledge controversies and discrepancies in the fields they are reviewing. With few exceptions, classic studies from the sixties and seventies are reported faithfully, with no mention being made of more recent work which casts doubt on the validity or generality of these findings. Again it is debatable as to whether an introductory text should sacrifice accuracy in the interest of clarity. Perhaps the most misleading chapter is that on psychological theories which gives the impression that such concepts as the Oedipus complex and operant conditioning are the cornerstones of contemporary thinking about human behaviour.

Despite these criticisms, the book has much to recommend it if used judiciously. Medical students and Membership candidates will find it a highly readable introductory text and, in view of the excellent index, it is ideal for quick reference and revision purposes. However, in view of its piecemeal style, the text adds little to our understanding of the complex issues surrounding symptom formation, illness behaviour and the design of individually tailored treatment programmes. Yet despite failing in their primary objectives, the editors have nevertheless produced a collection of useful introductory chapters which will be read avidly, and hopefully cautiously, by both undergraduate and postgraduate medical students.

DOUGAL MACKAY, *District Psychologist, Barrow Hospital, Bristol*

Pharmacotherapy of Affective Disorders: Theory and Practice. Edited by W. G. DEWHURST and G. B. BAKER. Beckenham: Croom Helm. 1985. Pp. 628. £40.00.

Books devoted to the topic of affective disorders have burgeoned over the past decade, reflecting the increased biochemical and pharmacological interest in this area. *Pharmacotherapy of Affective Disorders* is a multi-authored work, written in a large part by contributors from Canada and the United States, although there are three

European writers. The problem of many books with diverse authorship is the difficulty of maintaining links between the separate chapters. This is not wholly avoided in this volume, but there is a coherence about the contributions which makes it easier to assimilate than many books of this type. It is divided into sections dealing with the theories of the origin, epidemiology and diagnosis of affective disorders, the biochemistry of anti-depressants and actions and pharmacology of these drugs. The contributions are nicely shared between clinical and basic science workers from known centres of excellence.

The book provides an excellent reference to the biochemistry of affective disorders with very extensive discussion of classificatory schemes. A number of chapters would have been rendered more comprehensible by a summary of the main issues raised. In many ways the authors are not opinionated enough—it would be of value to know their own views about the merits of the various mechanisms and theories that they are discussing. This partly mirrors the conservatism and the caution of the Canadian editors, but it would not be out of place to guide the reader by indicating the credence of the evidence presented. Although often more readable than many North American contributions to the literature, some of the chapters suffer from lack of tabulation and figuration and the word processed print increases the impression of congestion making for irritating reading in one sitting. This seems to be the penalty for rapid publication.

The calibre of the book is reflected in its authorship, which includes such names as Flor-Henry, D. L. Murphy, Feighner, Lapierre and Bland, with contributions from our own Stuart Montgomery and Brice Pitt. All researchers in this area should have access to this book; psychiatrists and neurochemists will each find information of value in its sixteen chapters, and it should be widely quoted in *Citations Index*.

STEPHEN P. TYRER, *Consultant Psychiatrist,
Royal Victoria Infirmary*

Recent Advances in Postpartum Psychiatric Disorders.

Edited by DAVID G. INWOOD. Washington: American Psychiatric Press. 1986. Pp. 127. \$12.00.

It was the publication of James A. Hamilton's monograph *Postpartum Psychiatric Disorders* which whetted my appetite for the topic more than twenty years ago. Since then, however, American involvement in research in non-psychotic postpartum disorders has been very small compared with that in the United Kingdom and Scandinavia.

This little book is therefore at least to be welcomed as an indication that the Americans are getting in on the act, though I found the contents rather disappointing. In the first chapter the editor's classification which includes 'adjustment disorder with depressed mood (also known as maternity blues)' with an onset from the first day to six weeks postpartum, unfortunately blurs the distinction between 'the blues' and post-natal depression and suggests that 'peaking' of blues symptoms takes place at about the tenth day, when research indicates that it occurs on days

4-5. Two chapters give accounts of research which really belong in journals where they would have "the benefit of review by the scientific community". This phrase is taken from the chapter on 'Biological Aspects' by Jan Campbell and George Winokur which I found the most useful in the book.

It is nice to see a contribution by James Hamilton on 'Therapeutic Management' though I think he is too protective of patients against psychiatric labels (to the point of wanting to spare them a proper psychiatric interview) and I don't know why he has reservations about the use of tricyclic anti-depressants in serious postpartum depression. A robust account of a Mother and Baby Unit in the Royal Hallamshire Hospital, Sheffield by Joan Sneddon and R. J. Kerry, is surprising in the context suggesting that there is no comparable American experience to draw upon. Finally, there is a claim by another Dr Inwood for a bigger role for the paediatrician in the management of the peripartum than most of us would expect.

Members of the Marcé Society may be interested in a copy of this appropriate, modestly priced book, otherwise it will not attract many readers on this side of the Atlantic.

BRICE PITT, *Professor, Community Mental Health Unit for the Elderly, St Charles Hospital, London*

The Elderly in Modern Society. 2nd edition. By ANTHEA TINKER. Harlow: Longman Group. 1984. Pp. 369. £6.95

A second edition of this valuable handbook three years after the first reflects the importance of the 15% of our population over the age of 65 and the range and speed of the changes which affect them.

The book is intended not only for students of social administration but for all who are concerned with the elderly. Its 350 odd pages are packed with information needed by the very wide variety of disciplines so concerned and off-hand I cannot think of a more comprehensive dossier of sociological data, between the covers of a modestly priced paperback.

There is something here for everyone; for the psycho-geriatrician, the demographic background and chapters on health, personal social services, community care, evaluation and assessment are particularly useful.

Developments since the first edition was written in 1981 are conveniently considered in a 70 page final chapter and this is followed by a fascinating scrap book of 53 'documents' including apt quotations from Mark Abrams and Alex Comfort; observations on the elderly who are old, cold or found dead; suggestions by the elderly themselves about how they could be helped; snippets from the Beveridge & Seebohm reports and a variety of interesting tables.

A third edition must be due very soon and I look forward to it. My only suggestion other than 'more of the same' is that a better perspective could be given on how old people fare in our society by providing some information about what happens in other countries.

BRICE PITT, *Professor in the Psychiatry of Old Age, St Charles' Hospital, London*

Presentations of Gender. By ROBERT J. STOLLER, London. Yale University Press. 1986. Pp. 219. £23.00.

The title of this book could be misleading. It does present a sensible explanation for the development of gender identity, but the whole theory could be summarised in one sentence. Extremely feminine boys are, according to Stoller, the logical outcome of excessive and prolonged closeness with the mother and abandonment by a distant passive father. The main contributions of this book are, however, not this but it's critical appraisal of the analytic methods of research, it's questioning of the validity of psychoanalysis as a science and it's challenging of some of the most basic concepts in analytic theory. In this book, Stoller refutes one of Freud's most central views, namely that developmental arrest is caused by conflicts at a critical stage of psychosexual development. Stoller argues convincingly that non-conflictual gratification, e.g. a blissful and enjoyable relationship between a son and his mother, can lead to the developmental arrest of this son's masculinity. He also challenges the view that perversion is not possible until one has passed through oedipal conflict, by presenting a case of erotic fetishism in a two and half year old boy, the first case to be reported in analytic literature. Even more upsetting to the analysts is his challenge of Freud's belief that the male sex is the more superior, and that masculinity is the natural original mode of gender identity. In Freud's view the child grows up to be a boy unless his masculinity is interrupted. Stoller argues that it is femininity which is primary and that to become a boy the child has to sacrifice his femininity and give up his gratifying bond with his mother. He supports this view by clinical material, cross-cultural observations and by the biological fact that the foetus does not develop maleness unless androgen is added.

Apart from its theoretical and intellectual value, the book has very little practical value unless the reader is a practising analyst. The author does argue, however, against the liberal use of sex change and suggests treating the causes of the disorder rather than complying with them by allowing the patient 'to remain maximally and permanently ill'. Many clinicians will agree with him, but there is only one catch: he does not tell us how to do that!

Apart from minor irritations like the numerous footnotes, qualifications and explanatory statements which distract more than clarify and the fact that the book is written in the first person as if it is an autobiography, this book makes fascinating reading.

WAGUIH R. GUIRGUIS, *Consultant Psychiatrist,
Psychosexual Clinic, St Clement's Hospital, Ipswich,*

The Lead Debate: The Environment, Toxicology, and Child Health. Edited by RICHARD LANSDOWN and WILLIAM YULE. Beckenham: Croom Helm. 1986. Pp. 286. £25.00 (hb), £14.95 (pb).

This book tells us the many uses of lead today round the world, the precautions in collecting storing and analysing samples for lead and the provisos in interpreting the answers, the lead in waters, foods, air, paint, dust and other corners of the human environment, and the human physiology of lead. This forms an extensive background for reviewing in the last 80 pages the various attempts to define what lead may do in modifying the intelligence, attainment and behaviour of children. It is a dispassionate account, intended for a wide non-specialist readership (who may find it heavy going at times), which lacks however one extra chapter to spell out the economic and political implications of imposing controls on lead use: the balancing out of the risks and advantages of one act or another.

Although the book is called *The Lead Debate* it is much more useful than simply as a late starter to cool some of the passion roused by lead in petrol. Nearly everything it says applies in principle to the uses of nuclear power and radioactivity, or to other metals such as zinc, manganese, tin, cadmium aluminium, or lithium, which may be biologically inert at one level, possibly beneficial or even essential at another level, and toxic at yet a third. It is therefore helpful reading for psychiatrists as trace metals come to the fore in neuropathology and even in treatment.

Scientifically two complex issues stand out, the physiological and the psychological. The natural environment contains lead in various forms, and it is natural for the human body to contain some in its tissues and to metabolise it. The excretion of lead, and even more its gastrointestinal absorption depend on the diet: eat more iron (or more calcium) and you take in less lead. Hence, straightaway the difficulty of defining at what point exposure to lead begins to matter. Matter for what? Psychological tests are notoriously crude and imprecise, even of intelligence let alone of attention, memory, or personality, and on the other hand brain metabolism can stand a good deal of distortion from drugs and vitamins before (rather suddenly) behavioural abnormality appears. At what point does lead intake affect sleep or appetite or sex-life or work output? We are back in one of the central problems of psychiatry, how to quantify mental states.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

Vol 149

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrists

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG*.

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al.*, *British Medical Journal*, 7 May 1983, **286**, 1489-1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper**.

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full**. Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in *italic* and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and reference list are in complete agreement as regards dates spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that ...'.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In *Pathology and Treatment of Sexual Deviation* (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The design position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or original camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80-110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180-210 mm wide. Lettering (film-set or stencil) should be in 12pt sans (initial capital for the first word only) to give contrast on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unmodified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focused. Labels, arrows, etc. should be shown on a duplicate print overlay. Do not write anything on photographic prints. Do not use staples or paper-clips on them. These procedures apply to all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of the article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

UNIVERSITY OF SASKATCHEWAN

REHABILITATION PSYCHIATRIST REQUIRED

A Psychiatrist with a sub-specialty interest in Rehabilitation Psychiatry is required in the Department of Psychiatry, University of Saskatchewan, Saskatoon, Saskatchewan. This position will be a full-time appointment in the Department of Psychiatry at an appropriate rank and with benefits commensurate with the position. This incumbent will practise in the 534 bed University Hospital which has a 44 bed psychiatric inpatient unit, an active 25 placement day programme, and a twelve-member community nurse complement. The successful candidate will be responsible for the development of clinical, educational and research programmes in Rehabilitation Psychiatry for the Department.

Clinical involvement will include a major focus on the treatment and rehabilitation of individuals with long-standing or recurrent psychiatric disorders with significant disabilities.

Administrative aspects will include the directorship of a Rehabilitation Psychiatry Division in the Department and the maintenance and development of new community programmes, with particular emphasis on day programmes, community nurse management and vocational rehabilitation.

The educational responsibilities will be to undergraduate medical, post-graduate, family medicine and psychiatric trainees, in particular to the field of Psychiatric Rehabilitation.

There will be opportunities and encouragement of scholarly and research ventures. Presently, there are well established collaborative research programmes in Neuroscience, Pharmacology, Pharmacy and Epidemiology within the University, externally with the Research Division, Saskatchewan Health, and the Rehabilitation Division of the Department of Psychiatry, U.C.L.A.

In accordance with the Canadian Immigration requirements, priority will be given to Canadian citizens and permanent residents of Canada. Salary range will be commensurate with qualifications and experience.

Please address enquiries to:

D. L. Keegan, M.D. F.R.C.P.(C), Professor and Head, Department of Psychiatry, University of Saskatchewan, SASKATOON, Saskatchewan S7N 0X0. (306) 966-8253

UNIVERSITY OF LONDON
Institute of Psychiatry

TRAINING COURSE IN COGNITIVE BEHAVIOURAL THERAPY

There will be a training course in Cognitive Behavioural Therapy at the Institute of Psychiatry between February and July 1987. The course starts with a two-day workshop on 20 February and 21 February, and thereafter every Friday morning between 9.30 am and 12.30 pm, until 23 July.

Students will be expected to treat patients under supervision, and will attend a series of academic seminars. Psychiatrists and post-qualification psychologists are likely to be particularly interested, though applicants from other professional disciplines will be considered. Numbers will be limited.

For further details apply to the Registry, Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF.

Caring for the patient with special needs.

LANGTON HOUSE

Adolescent and Young People's Unit

A community that offers assessment and treatment programmes for behaviourally disturbed adolescents and young people. Special emphasis is placed on education and rehabilitation likely to be of benefit to residents when they return to their own community.

Durnford Drive, Langton Matravers, Swanage, Dorset, BH19 3AG

**PROVINCE OF BRITISH COLUMBIA, CANADA
MINISTRY OF HEALTH**

PSYCHIATRISTS

Mental Health Services in British Columbia has recently announced the amalgamation of their primary in-patient psychiatric hospitals (Riverview and Valleyview). This new hospital is organized into adult and geriatric divisions and invites qualified applicants (FRCPC or MRC Psych) to direct a broad range of multi-disciplinary programs, including assessment, acute care, continuing treatments and community preparation for a total patient population of approximately 1200. Research and educational programs have been developed as an integral part of the activities of each division.

Both salaried and contract appointments are available with potential earnings up to \$90,000 Cdn. per annum. Facilities are located twenty minutes east of Vancouver.

Reply with a curriculum vitae to Dr. J. E. Runions, Clinical Director, Riverview Hospital, 500 Lougheed Highway, Port Coquitlam, B.C. Canada V3C 4JC immediately.

**UNIVERSITY OF LONDON
INSTITUTE OF PSYCHIATRY**

**DIPLOMA IN ADDICTION BEHAVIOUR
AN INTERNATIONAL TEACHING
COURSE**

The Institute of Psychiatry offers a full-time one year course leading to a Diploma in Addiction Behaviour starting October 1987.

The Course has a strong international and multidisciplinary focus. It covers alcohol and drug problems and offers clinical and community placements. It integrates teaching on basic sciences, clinical aspects, design and running of treatment services, prevention and development of national policy. Though primarily intended for medical staff, other professions with clinical experience will be considered. Clinical teaching takes place at the Bethlem Royal and Maudsley Hospitals, Charter Clinics and St George's Hospital's Department of Addiction Behaviour.

Course Director: Professor Griffith Edwards.

Seminar leaders include: Dr Virginia Bernidge, Dr J. Cutting, Professor G. Edwards, Dr H. Ghodse, Dr Ilana Glass, Mr A. Glanz, Mr M. Grant, Dr R. Hartnoll, Professor M. Lador, Professor J. Littleton, Dr R. Murray, Ms Edna Oppenheimer, Dr J. Orford, Professor D. Robinson, Dr M. Russell, Dr I. Stolerman, Dr T. Stockwell, Dr J. Strang.

Application forms and further information about the Course including fees are available from the Course Organiser: Dr Ilana Glass, Addiction Research Unit, Institute of Psychiatry, 101 Denmark Hill, London SE5 8AF.

**QUEENSLAND PUBLIC SERVICE DEPARTMENT OF
HEALTH**

**MEDICAL SUPERINTENDENT
BAILLIE HENDERSON HOSPITAL
TOOWOOMBA—QUEENSLAND
AUSTRALIA**

(Reference No. 1389V86)

A Medical Superintendent is required for the Baillie Henderson Psychiatric Hospital, Toowoomba, Queensland. This hospital has 470 beds and in addition provides Community based and outreach psychiatric services for Toowoomba and South West Queensland. The service also provides professional support for a 25 bed inpatient unit at the Toowoomba General Hospital and its outpatient and consultation-liaison services. Psychogeriatric and general psychiatric day hospitals are centrally located in the city.

The role of the Medical Superintendent covers administrative, clinical and teaching responsibilities. The hospital is an accredited training centre for the Royal Australian and New Zealand College of Psychiatrists, and has an active training programme.

The psychiatric hospital itself caters for a limited number of acute inpatient admissions, medium to long term rehabilitation of psychiatric patients including those with alcohol related problems and psychogeriatric patients, as well as a unit for the young brain damaged persons with behaviour problems. A Unit for intellectually handicapped persons is also sited on the hospital campus.

Toowoomba is a very attractive city with a population of 74,500, within two (2) hours driving time of Brisbane. It is renowned for its civic pride, schools, restaurants, and the annual Carnival of Flowers. It is the gateway to the rich farming area of the Darling Downs.

Classification is I-27 under the Public Service Award and salary at present is \$59,984 per annum. Usual Queensland Public Service conditions apply (e.g. compulsory superannuation, 5 weeks annual leave etc). A hospital residence together with milk, vegetables, fuel and light is available free of charge.

Financial assistance towards removal expenses may be provided to appointees from other States or overseas. Applicants must be registered or eligible for registration as a medical practitioner in the State of Queensland and must hold appropriate postgraduate qualifications in psychiatry. Administrative experience would be an advantage.

Further particulars may be obtained from Dr. P. J. Tucker, Assistant Director-General (Mental Health Services) and Director of Psychiatric Services, State Health Building, Brisbane on (07) 227-7537.

Applications should be made containing full particulars of name, address, telephone number, date of birth, marital status, qualifications, experience and present employment and furnishing copies of testimonials and the names of two referees.

Envelopes should be marked 'CONFIDENTIAL' and be forwarded to: Advertised Vacancy Officer, Department of Health, 14th Floor, State Health Building, 147-163 Charlotte Street, BRISBANE. Q. 4000. Closing Date: 5.00 pm Monday 22 December 1986.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine¹, trifluoperazine² and haloperidol³, but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia⁴.

^{sulpiride} DolmatilTM IN SCHIZOPHRENIA

Prescribing Information Dolmatil Tablets Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 200mg sulpiride. **Indications** Acute and chronic schizophrenia. **Dosage** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and early evening) is recommended. **Predominantly positive symptoms** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily. **Predominantly negative symptoms** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily. **Mixed positive and negative symptoms** 400mg-600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment. **Clinical experience** children under 14 years of age is insufficient to permit specific recommendations. **Contraindications** Phaeochromocytoma. **Warnings** Extrapyramidal reactions principally akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary. After a decade of widespread use in many countries, tardive dyskinesia has occurred rarely. Insomnia has been reported, increased motor agitation has been reported. A dosage in a small number of patients in aggressive, agitated or excited phases of the disease process. Dolmatil may aggravate symptoms. Care should be exercised where hypomania is present. Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions** Epilepsy - anti-convulsant therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney. **Pregnancy** - the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number** PL 5299/0006 **Legal category** POM **Basic NHS price** 63p per day at dose of 600mg daily. **Name and address of Distributor** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW4 6JF. **Trade Marks** of E R Squibb & Sons Ltd (Distributor) DOLMATIL - Trade Mark of SESIF Authorised User Delagrangue Ltd. **References** 1. Adolf Meyer

Some Recollections and Impressions

J. WORTIS

Adolf Meyer was famous when I first met him in 1933. I was at that time a psychiatric resident at Bellevue Hospital, and Meyer was Psychiatrist-in-Chief at Johns Hopkins Hospital. He had been asked by the sponsors of a fellowship I was given to act as guide and supervisor, and had agreed. I met and corresponded with him throughout the tenure of that fellowship, to 1940, spending a year in his department in Baltimore in 1938-1939, and saw him irregularly thereafter.

His department at Johns Hopkins was the most prestigious in the country: everybody aspired to train there. He sat on nearly every committee of importance, on editorial boards, on important commissions, and his advice was sought for many key professorial appointments at leading universities. Though Meyer was well aware of his authority, his bearing was modest and simple. In his office he would not address you from a big chair behind his desk, but placed you in an easy chair, while he moved to an ordinary chair himself. He was short of stature, with thin hair and high forehead, wore a Van Dyke, spoke with a German-Swiss accent, and was very much the European professor.

He was not the kind of person who called you by your first name on brief acquaintanceship: we knew each other for 15 years, but he never addressed me by my first name. He was abstemious in his habits, started his day early, worked through the luncheon period and left a little early when his wife, who drove the family car, generally called for him. He regretted the separation of home and place of work. "When you live away from your work place," he remarked, "you lead a divided life." He did not smoke, and I do not think I ever saw him drink a cocktail, or indeed any wine. At large social gatherings it was generally Mrs Meyer who would maintain the conversation: Meyer was more passive, and would remain observantly quiet or responsive to attentions. He seldom engaged in casual conversation with members of the house staff, but would invite all of us in small groups in succession to have dinner at his home once a year.

His manner was always mild. He was a good listener, and when he spoke was never peremptory,

but cautious and moderate in his pronouncements, modifying or qualifying his phrases to produce a very characteristic circumlocution. His thinking also seemed to be many-faceted and complex rather than incisive or decisive, a quality that hampered his writing ability. He used to complain that he was educated in too many languages and could never attain literary proficiency in one, but I think the real difficulty was his tendency to excessively complex formulation.

Adolf Meyer had entered the American scene at the turn of the century at a crucial point in American psychiatry. There was on the one hand the vast custodial system for the psychotic in the state hospitals, and on the other hand the private practising neurologists (like Weir Mitchell) who were being called upon increasingly to deal with 'neuroses'. Aside from the state hospital system, psychiatry was privately practised by the neurologists. Scientific activity in psychiatry was mostly limited to descriptive or nosologic interests (Kraepelin) or to neuropathology. The new psychodynamic trend (Janet and Freud) was just beginning to emerge. At this juncture Meyer, based in the state hospital system, schooled and distinguished in neuroanatomy and neuropathology, and committed to the biographic individualized approach to case study, embodied the special combination of background and interests that the times required. The creation of a psychiatric chair for him at Johns Hopkins was innovative and set the pattern for similar developments in medical schools throughout the country.

He gathered a remarkably good staff around him. It was not only that Meyer picked good people: the most promising or best connected people also sought him out. Dr Esther Richards was perhaps the first woman to hold an important post in the Johns Hopkins faculty (the Phipps Clinic always had a high representation of women), Richter, Gantt, Diethelm, Muncie, Rennie, Kanner, Katzenelbogen and others all made their mark, and innumerable distinguished careers—both American and foreign—began there. For a long time there were always a few young residents from Britain in training there, and other foreigners came and went.

Though Meyer was by no means a system builder, the Phipps Clinic was a model of quietly efficient operation, achieved in an atmosphere of friendly relaxation. Everything had its place and everybody his or her role. Commands were not issued, but things were expected and had to be done, otherwise you would be embarrassingly conspicuous. The morning conference in the little library for example would start at nine: if you came late, everybody would see, and you would miss part of the presentation. Before nine Dr Meyer would regularly confer with his senior staff in his office, where news would be exchanged and decisions made: nothing of importance escaped attention. The non-professional staff was stable and loyal and stayed on for years. Senior staff similarly had little turnover. If there were rivalries and factions they were kept within discreet and polite limits, though Meyer once told me with a mischievous smile that whenever anybody left the staff he had a feeling of relief.

Meyer opposed the formal diagnostic preoccupations of the Kraepelinians, came to oppose the extreme and intense psychodynamic concerns of the psychoanalysts, and moved psychiatry a considerable distance from medicine. Though he maintained a broad all-inclusive frame of reference for psychobiology, in practice he discouraged and discounted the medical dimension. He refused to admit cases of general paresis to the Phipps Clinic because he considered them essentially medical problems. He maintained his love for neuroanatomy (every resident was expected to make a plasticine brain model under his tutelage) but considerations of neuroanatomy or neuropathology practically never arose in clinical conference, and I recall one case of brain tumour in an inpatient at the Phipps Clinic that was long undetected. The psychophysiological laboratories of Richter, Katzenelbogen, and Gantt intruded hardly at all into the clinical thinking at Phipps. As an example of Meyer's catholicity of interest they told a story of an announcement at the Phipps Clinic of a lecture at the hospital on 'The Chemistry of Doubt'. Nobody showed any surprise, until it was disclosed that it was all a typographical error: it should have read "The Chemistry of Gout".

With the widely publicized advent of insulin shock therapy, Meyer was quite seriously concerned, for he regarded this as a threat of resurgent medical emphasis in an area where he felt humane psychological interest should prevail. He accepted an invitation to speak at a meeting at the New York Academy of Medicine devoted to the sensational new treatment, but wrote me (1937):

There are two extremes in the attempts to play the savior role in psychiatry: work at the root—which is evidently *not* insulin work—and importations which have next to nothing specific to do with psychiatry but exploit the patient and resources through and for imported interests; and this is the case with insulin. I am always sorry to see the latter get on the top. Whenever it does, my interest wanes. I have allowed the paresis problem to pass into the domain of the lues department because paresis is a 'dirty' experiment of nature without localizing or any other control being possible. I am willing to leave it to the spirochaetist. And with insulin we deal with even more of an importation apt to divert the attention completely from the illness by absorbing the attention in the direction of something pharmaceutical. I am not belittling the interest and the experiment, but I hope you understand me fully.

It is too easy for non-psychiatrists to assume a dominant position and to become more or less antipsychiatric in the field. Therapy by the way of experimental pathology, along lines which have nothing to do with the disease process except as a starter and in the role of medical dominance acceptable to the patient and relatives and the profession will always have to prove itself. As soon as it becomes dominant by diverting the attention from what after all is the crux of it all, viz., the therapy at the root and in terms of life, it should only hold itself if success justifies the always disturbing disruption and usurpations by some narrow technician. I naturally shall not inject this note into the discussion of January 12. The meeting will anyhow be one *in partibus infidelibus*; i.e., governed by non-psychiatric interests and all I can expect to do is not to stir up the problem of psychiatry, but to balance what is sound in the work.

When insulin treatment was finally used at the Phipps Clinic, and the results were positive, he discouraged publication.

Meyer did bring into his conferences a broad medical culture and a strong moral commitment. His wide travels, his knowledge of languages and his studious habits gave him a breadth of information, much of it based on personal knowledge, that raised his discussions to a high level. At the same time it came as a pleasant shock to me, after my years at Bellevue Hospital, to hear Adolf Meyer insistently ask after every case presentation, "What are we going to do for this patient?" a query that was seldom heard amidst the prevailing psychodynamic interests in New York City.

Meyer's remarks at the daily morning conferences were often rambling and hard to understand. I sometimes felt like the little boy in "The Emperor's New Clothes" and was tempted to cry out that the emperor had nothing on, but deference to the aura of his presence was too pervasive to be dissipated. Actually the aura, in spite of its diffuseness, was beneficent; one could get the drift even when the details were obscure: the fog was luminous. The drift

generally involved an eminently humane effort to see a patient's symptoms and problems in the full context of his past life and present situation, to approach him sympathetically, to utilize his positive attitudes and assets and to teach, guide, assist in any way that would help the patient to return to his society and to his social goals.

Meyer's prominence and moral commitment often lead to cautious involvement in liberal causes. The involvement was always cautious because Meyer respected the established order and would do nothing that might appear to be disruptive. He was identified in those years, for example, with the effort to develop friendly relations with the struggling new socialist proletarian USSR, but at the same time was much disturbed by the attempts of some physicians at Bellevue to join a bargaining union. I am sure he did not think he was tainted by any racial bias, but he acquiesced to local custom: no Negro was ever admitted to the Phipps inpatient service, and Blacks held only menial jobs at the Clinic.

He had no interest in private practice, and was a strong believer in medical planning, in preventive medicine, in the public health model, and in government participation in all levels of health service. He wrote to me (1937):

The ideal of medicine is to make itself unnecessary. I wish it could be taken out of the economically competitive ranks. But in a power-crazy period the power-craze will be a deplorably strong item if not a necessity, whether under the sheepskin of "communism" or under the bald display of dictatorship, both living on might and hatred. It looks as if a new species of animal ought to sweep aside the present 'regimes'. The problem of self-maintenance of worker and work is difficult to solve since the sound features of 'bourgeoisie' were corrupted by greed and anti-greed and supergreed.

In an earlier letter to me (1934) he wrote:

Science has played too lone and high and mighty a game; so has industry and so have the humanities. They made puppets of man and are reaping their harvest. And who are 'they'? *We*, who are part of them and have to learn to sense the responsibility.

He preserved a polite but distant relationship with his fellow Swiss professor at Johns Hopkins, Henry Sigerist, whose book on Soviet Medicine was causing a stir. In spite of his general approval of government support of health services, he tried to dissuade me from joining an effort to set up a conference at Johns Hopkins in 1938 to promote national health insurance, because it was associated with Sigerist's name and was regarded by some as radical. He was

strongly opposed to the rising threat of Hitlerism, and devoted one morning's conference in 1938 to a discussion of Hitler. The occasion was a telegram he received from one of the Washington news agencies asking whether he thought Hitler was psychotic. The formulation of his response was typically Meyerian: The trouble was not that Hitler was diseased, but that he was healthy. And yet, Meyer went on to say, he had a disorder, and the cause of his disorder was his success: the treatment must therefore be his failure.

Another worthy cause for which Meyer's help was solicited (in 1938) involved the effort to rally support for a well known musician who had been sentenced to a very harsh long term of imprisonment because of a homosexual act. Meyer asked me to visit the prisoner and to prepare a report on the case, and was very helpful in securing his parole, and later his pardon. In asking me to report on the case, he wrote:

That some humans are homosexual may be completely beyond their control, either a matter of start (or heredity-determined spontaneity), or due to particular factors in habit-formation, special experiences such as seduction, or owing to narrowing factors in the sex opportunities and tendencies, or by venture and accident, and unwillingness to know and live up to the rules and laws of the body social. What then are the facts that bring the case to observation and judgment? The first concern to me in such a case is the nature of the charge and the facts at hand.

Without specification of the events I should not consider the mere accusation: solicitation and seduction and corruption? Public nuisance? Likely to have caused damage or to forebode damage to additional victims? In what way and to what extent is his case different from the partner? What is to be punished and what to be attained and how? For the protection of society? For treatment of his predicament? As a public deterrent (in general principle or as a clear demonstration of what the facts are and what the law aims to cover)? What does the letter of the law allow in the way of latitude? Were there ever any efforts to get treatment before or since the events and what would such 'treatment' aim at? What evidence is there on the question of dependability in the past and in case of release? It may be that your conversation and discussion of the case and the facts furnished give the picture needed. I lack the data. It may have been mutual masturbation with a minor? I should like to make clear that my letter will be based on an intimate knowledge of the facts of the case.

He had his own mild style of waging polemics. One adversary would mimic Meyer by saying, "Never mind the theory: let us have the facts. What you believe is theory; what I believe is fact." Meyer for his part said this person reminded him of Charlie Chaplin (to whom he did indeed have a certain resemblance). Of another unfriendly soul, he simply said, "He is not a man of strong personal

attachments." He wrote to me when I was seeing Freud in Vienna:

Freud interested me from his debut in the literature and while I felt from the beginning of my medical work keen on the inclusion of all of human nature in the scientific reality and objective world even just as I found it, the systematic organization he gave to it all was and is always stimulating and like a fabric of true art and life. I saw and heard him at Worcester in 1909 and called on him in 1923 and regret that the personal contacts could not have been more frequent and closer. I hope you will be a live link to whom I may turn when you get back to these shores. To cover such a life-work with the author while you allow yourself to vibrate true to yourself and to the atmosphere must be a great satisfaction.

When I complained of what I regarded as Freud's narrow dogmatism, he wrote:

Do not let yourself be misled by the natural concentration and limitation Professor Freud puts on himself. It is a mixture of temperament and wisdom and fate, which had best be accepted so that it gets its fullest expression. I sometimes envy that capacity; at any rate I see its great force, actually I am able to put myself in the position of the varieties of personalities and movements without any sense of resentment, although one regrets at times the lack of reciprocity. I should give a great deal to have or to have had your opportunity so as to be in a position to be thoroughly fair toward a force that crystallized some of the most fateful meanderings—perhaps too fatefully. I understand your dilemma, but trust that you can get a most interesting sense of the principles in pure culture without loss to your ultimate digestion of it all.

Because of his special prominence his chairmanship was renewed year by year after normal retirement age, but he finally began to fail, and his successor John Whitehead was appointed. Though Meyer was invited to retain his beloved neuroanatomy laboratory, he made little use of it, and was offended by what he regarded as Whitehead's excessive independence. When he was struck down by a cerebrovascular accident soon afterwards he made only partial recovery and never fully regained his faculties.

In June 1948 my wife and I had occasion to spend some time in Baltimore; I thought I would revisit Meyer. I knew that Meyer was an aged invalid; then in his 82nd year, and that this might be my last opportunity to see him. I sent a note ahead to which Mrs Meyer responded cordially asking us to join them at dinner. Since I recorded some notes in the evening after returning to our hotel, I can recall many details.

We found Mrs Meyer as vivacious and hospitable as ever; their daughter Julia and grandchild Kiki

were there as well as Dr Meyer's devoted former neurological laboratory assistant. We arrived a few minutes late and Mrs Meyer told us that Dr Meyer already had to take his seat at the table because it was so hard for him to get about. He sat with a napkin pinned to both of his lapels looking pathetically like an animated wax effigy bearing a certain resemblance to his former self.

Mrs Meyer took the initiative at the table conversation, with Dr Meyer from time to time making amiable and measured remarks, sometimes of questionable relevance and intelligibility. Very early in the evening he described his neurological disability as "a hemiplegia without hemiplegia." He went on to explain that he could grasp an object such as a glass quite well and could negotiate it, but could not control involuntary movements: his right hand jolted whenever he coughed. He said he found he had more dexterity if he twisted his head and body around to the left and he persisted in repeating these neurological observations about himself throughout the evening, later rising three times to demonstrate his prowess. He appeared to have no realization of any intellectual decline and even said explicitly that his conscious thinking processes were quite intact.

He displayed very little curiosity about anything I was doing, and spoke casually of his own isolation and of the disfavour in which the psychoanalysts seemed to hold him "because I was never analysed." "Grinker was here" he said, "sitting right here at the table. He is a somewhat colourful person who has given himself a name but I felt somehow that we were not in agreement." Indeed Meyer spoke in a friendly way of a whole series of associates and common acquaintances and did not say a harsh word about any of them. Of Whitehead he said with what sounded like a remote approximation to bitterness, "He has been here just twice." He remarked gratefully that "the neurological association seems to have remembered me," a reference to his recent election as an honorary member of the New York Neurological Society.

I recall his saying, "The analysts are always interested in putting things in their place. I have always wanted to put things together to see the relationship of things." He deplored the fact that no one seemed to be at hand to explore his neurological disability systematically. "Why don't you do it yourself?" I asked. "One cannot examine one's own unconscious," he replied, "You cannot study your own sleep, because you are asleep." With typical perseverance he came back to the phrase about examining one's own unconscious again and again.

He seemed to approve of my derogatory reference to private psychiatric practise as an unfortunate necessity, but when I spoke of the emerging interest in social psychiatry he said, "You have to be careful not to give it a political connotation." He stretched his hands forth as if arranging something on the table and added enigmatically, "There is communism, and yet I am not a communist."

Toward the end of the evening he said, "My library is in order, I have my study and my books where anyone who wishes to read may come. But," he went on, shrugging his shoulders, "who will want to come?" Later he said, "Death is an indeterminate sentence. It may come in 24 hours, though that is unlikely, but still," he repeated, "death is an indeterminate sentence."

This was an evening with the invalid Adolf Meyer some 20 months before he died. In retrospect little that was meaningful was said. There was not a single reference to any important current event nor was any important relationship with anybody described. There was in a sense something hollow about the occasion, but there was still something about Meyer which suggested an epoch, a breadth and a certain grandeur.

Joseph Wortis, MD, *Department of Psychiatry, State University of New York at Stony Brook, 152 Hicks Street, Brooklyn, New York 11201, USA.*

(Accepted 12 June 1986)

His thoughts were still immersed in his past work and interests. Since Meyer had always been opposed to medical overemphasis in psychiatry it seemed ironic that his efforts to recall the past were so hampered and fragmented by his neurologic failings. He was aware only of the motor components, but the diffuse and elusive quality of his talk seemed like a caricature of his earlier tendency to complex and sometimes perplexing expression. "I have a hemiplegia" he had told me that evening, "but no alexia. I have no agraphia because I can write in a scribble though it is hard, but still I can write. I feel there is a difference between my sides, but what it is I do not know. Something is lacking, but I do not know what. A man cannot read his own unconscious."

He added, I thought perhaps significantly, that in 1933 following the Detroit psychoanalytic meeting he first noted a difference between his sides. I had the disturbing thought that a slight asphasic insult may have developed at that time which was glossed over respectfully through the years by the many devoted pupils and associates.

Subcortical Dementia

Neuropsychology, Neuropsychiatry, and Pathophysiology

J. L. CUMMINGS

Subcortical dementia refers to a clinical syndrome characterised by slowing of cognition, memory disturbances, difficulty with complex intellectual tasks such as strategy generation and problem solving, visuospatial abnormalities, and disturbances of mood and affect. The syndrome was first described by Kinnier Wilson, but further progress in development of the concept has occurred only within the past ten years. Subcortical dementia occurs in degenerative extrapyramidal disorders and has also been identified in inflammatory, infectious, and vascular conditions. Histologic, metabolic, and neurochemical investigations implicate dysfunction primarily of subcortical neurotransmitter systems and subcortical structures or subcortical-frontal connections in the genesis of the syndrome. Subcortical dementia contrasts neuropsychologically and anatomically with disorders such as dementia of the Alzheimer type that affect primarily the cerebral cortex. The clinical characteristics of subcortical dementia reflect the interruption of fundamental functions (motivation, mood, timing, arousal) mediated by phylogenetically and ontogenetically early maturing structures.

Dementia is an acquired persistent impairment in intellectual function involving several domains of mental abilities and resulting from brain dysfunction (Cummings & Benson, 1983). Dementia was once regarded as a unitary disorder of brain failure with homogeneous mental status alterations, but recent studies of intellectual changes in specific disease processes reveal that dementia has variable manifestations and that the nature of the cognitive and behavioural alterations can be correlated with the distribution and severity of brain pathology. Preliminary investigations have demonstrated two principal patterns of neuropsychological deterioration within the dementias: 1) a cortical pattern with intellectual decline including loss of such abilities as language, learning, perception, calculation, and praxis and manifested by aphasia, amnesia, agnosia, acalculia, and apraxia; and 2) a subcortical pattern resulting from disturbances of functions such as motivation, mood, attention, and arousal evidenced by psychomotor slowing, memory impairment, affective and emotional disorders, and difficulties with strategy formation and problem solving. Anatomically, the cortical pattern is produced by diseases involving primarily, but not exclusively, the association cortex of the cerebral hemispheres and the medial temporal lobes, whereas the subcortical pattern occurs in disorders with predominant

involvement of basal ganglia, thalamus, and brainstem structures (Albert *et al*, 1974; McHugh & Folstein, 1975; Albert, 1978; Cummings & Benson, 1983, 1984). Alzheimer's disease and Pick's disease are examples of cortical dementing processes; the dementia syndromes associated with the extrapyramidal disorders (Huntington's disease, Parkinson's disease, progressive supranuclear palsy, etc.) exemplify the subcortical pattern of intellectual impairment.

The relationship of dementia to cortical dysfunction is widely known and accepted, whereas the correlation between subcortical pathological involvement and dementia is more controversial. This review will present the available information regarding subcortical dementia and the contribution of subcortical structures to human intellectual and emotional function. A brief history of the idea of subcortical dementia will be presented first; followed by a discussion of the neuropsychological and neuropsychiatric characteristics of subcortical dementia; finally the pathology, pathophysiology, and possible mechanisms of subcortical dementia are described.

History of subcortical dementia

Subcortical dementia was first described by S. A. K. Wilson in 1912. In the course of describing the

disease that came to bear his name, Wilson commented on the "psychical symptoms" and noted that in contrast to "senile dementia" and dementia paralytica, his patients had no evidence of agnosia or apraxia, and memory and comprehension deficits were less severe. They manifested "narrowing of the mental horizon" manifested by a diminished capacity to store and retain mental impressions, and they evidenced "facility, docility, and childishness" with lack of insight and poor judgment. He observed that the symptoms closely resembled those occurring in Huntington's disease and Parkinson's disease. At autopsy, Wilson's patients had severe pathological changes in the lenticular nucleus and globus pallidus; the cerebral cortical structures were preserved. Thus, in addition to establishing the relationship between an extrapyramidal movement disorder and disease of the basal ganglia, Wilson must also be credited with the first description of a syndrome now recognised as subcortical dementia and with demonstration of its association with basal ganglionic dysfunction.

After Wilson's initial contribution linking intellectual impairment to basal ganglia disorders, observations regarding dementia in patients with thalamic and basal ganglionic diseases continued to accumulate, but no systematic formulation of the relationship was attempted for approximately 60 years. In nearly simultaneous publications, Albert and colleagues (1974) and McHugh & Folstein (1975) called attention to the subcortical origin of the dementia of progressive supranuclear palsy (PSP) and Huntington's disease, respectively. Albert *et al* (1974) noted that patients with PSP typically exhibited forgetfulness, slowness of thought processes, alterations of mood and personality, and impaired ability to manipulate acquired knowledge. They emphasised the absence of cerebral cortical involvement in PSP and observed that similar behavioural alterations had been described in patients with other subcortical degenerative processes such as thalamic degeneration, olivopontocerebellar atrophy, and Parkinson's disease and that all these disorders failed to produce the aphasic, agnostic, and apractic deficits characteristic of dementias associated with cortical dysfunction. Similarly, McHugh & Folstein (1975) described abnormalities of problem solving, insight, judgement, abstraction, attention, concentration, and motivation in patients with Huntington's disease. They contrasted these deficits with the aphasia, alexia, apraxia, and agnosia of Alzheimer's disease and with the amnesia of the Wernicke-Korsakoff syndrome. Noting the prominence of subcortical degeneration in Huntington's disease and the relatively limited and variable cortical involvement, they suggested that

the mental changes were a product of the subcortical pathological alterations.

In the past decade, the seminal observations of Albert *et al*, (1974) and McHugh & Folstein (1975) have been supported and extended. Among the extrapyramidal syndromes, subcortical dementia has been found in Parkinson's disease (Albert, 1978), idiopathic basal ganglia calcification (Cummings *et al*, 1983), and spinocerebellar degenerations (Hart *et al*, 1985) as well as PSP, Huntington's disease, and Wilson's disease. Thalamic degeneration, likewise, produces a similar pattern of intellectual deterioration (Stern, 1939; Schulman, 1957; Katz *et al*, 1984). Subcortical dementia has also been identified in non-degenerative disorders: infarction of the basal ganglia and thalamus produces the characteristic mental status syndrome (Cummings & Benson, 1983; Guberman & Stuss, 1983; Graff-Radford *et al*, 1984), and similar behavioural changes have been observed in patients with granulomatous and post-encephalitic involvement of the same region (Pilleri *et al*, 1981; Hier *et al*, 1983). Among metabolic conditions, the subcortical pattern of dementia has been identified in parathyroid dysfunction where basal ganglionic calcification is often prominent (Bachman & Albert, 1984). This aetiologically heterogeneous group of disorders shares a similar pattern of intellectual compromise and a common preferential involvement of subcortical grey matter structures.

Characteristics of subcortical dementia

Neuropsychological and neurobehavioural aspects

Dysfunction of subcortical structures results in abnormalities in speed of information processing, attention and concentration, memory, word list generation, abstraction and categorisation, judgement, problem resolution, strategy formulation, and visuospatial abilities. The dementia syndromes of Parkinson's disease and Huntington's disease have been studied most extensively and will be cited to provide examples of these deficits.

Speed of cognition

Slowness of central processing is a ubiquitous abnormality that contributes to many of the deficits of subcortical dementia. Originally considered a reflection of retardation of movement (bradykinesia), recent studies have shown a slowness of information processing (bradyphrenia) in excess of the motor system abnormalities. Evarts *et al* (1981) compared parkinsonian patients with aged controls

matched for severity of motoric slowing and found that the Parkinson's disease patients had significantly slower reaction times indicative of slowed central operations. Wilson *et al* (1980) demonstrated that the speed of memory scanning is increased in elderly Parkinson's disease patients compared to elderly control subjects, and Horne (1971) showed that post-thalamotomy Parkinson's disease patients had normal reaction times for tasks with no response delay but were significantly slower than control subjects when the tests were made more complex by requiring a delay in response. Rafal *et al* (1984) failed to demonstrate a retardation of central processing in their patients, but they found that dopamine treatment improved performance on two complex reaction time tasks and did not facilitate simple reaction times, suggesting that abnormalities of dopaminergic function were contributing to response latencies of the more complicated procedures. Stern and colleagues (1984) found a significant relationship between reaction times and abnormalities of norepinephrine metabolism in Parkinson's disease patients.

Slowing, unrelated to motor disturbances, has also been noted in patients with Huntington's disease and PSP (Rafal & Grimm, 1981; Brouwers *et al*, 1984).

Attention and concentration

Attention, concentration, and vigilance may also be disturbed by dysfunction of subcortical mechanisms. Parkinson's disease patients may manifest abnormalities on tests of concentration including digit span, digit symbol, trail making tests, and serial cancellation tasks (Reitan & Boll, 1971; Pirozzolo *et al*, 1982), and patients with left-unilateral Parkinsonism exhibit disturbances of visual attention and cancellation (Villardita *et al*, 1983). McHugh & Folstein (1975) emphasized that Huntington's disease patients had abnormalities of attention and concentration that contributed to their memory and cognitive deficits.

Memory

Memory disturbances are a cardinal feature of subcortical dementia but have been only partially characterised and contrasted with memory abnormalities in cortical dementing illnesses. While remaining oriented and performing adequately on simple memory tests, Parkinson's disease patients explored with more detailed testing manifest abnormalities in visual memory, learning of superspan word lists, logical memory, paired associate learning, tactile memory, and recall of remote personal and

sociopolitical information (Warburton, 1967; Reitan & Boll, 1971; Pirozzolo *et al*, 1982; Freedman *et al*, 1984; Globus *et al*, 1985). The deficits in recall of new information are partially aided by cues and by choice recognition manoeuvres suggesting a greater deficit in recollection of stored information than of encoding new material (Tweedy *et al*, 1982). Impaired recall of remote information is equally severe for all decades of the patient's life; the temporal gradient characteristic of Korsakoff's syndrome is lacking (Freedman *et al*, 1984). A relationship between altered catecholamine function and memory impairment in Parkinson's disease is suggested by the correlation between memory performance and cerebrospinal fluid catecholamine metabolite ratio (Mann *et al*, 1983) and the observation that verbal memory performance improves following levodopa administration (Marsh *et al*, 1971; Halgin *et al*, 1977).

Memory disturbances in Huntington's disease resemble those of Parkinson's disease. Impaired performance in tests of recent memory are among the earliest detectable abnormalities of Huntington's disease patients, and analysis of the recall deficits suggests disturbances in both encoding and retrieval (Caine *et al*, 1977; Butters *et al*, 1978). Compared with Korsakoff's syndrome, patients with Huntington's disease show no improvement with reduced proactive interference but are significantly aided by using recognition as opposed to recall paradigms (Butters *et al*, 1976; Martone *et al*, 1984). Like Parkinson's disease patients, those with Huntington's disease have remote memory deficits involving all decades (Albert *et al*, 1981). There is a significant correlation between the severity of memory abnormalities and the extent of caudate atrophy seen on computerised tomographic (CT) scans of the head of Huntington's disease patients (Sax *et al*, 1983).

Memory abnormalities have not been as well studied in other subcortical dementing disorders, but slowed memory scanning is evident in patients with Friedreich's ataxia, and memory is impaired in PSP (Albert *et al*, 1974; Davis *et al*, 1985; Hart *et al*, 1985).

Visuospatial abilities

Visuospatial deficits not attributable to motor system abnormalities including visual discrimination, visual organisation, spatial orientation, drawing, angle perception, and rotational task disturbances have been identified in patients with Parkinson's disease (Mortimer *et al*, 1982; Pirozzolo *et al*, 1982; Boller *et al*, 1984; Globus *et al*, 1985). Parkinsonian patients also have difficulty judging vertical and horizontal

When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

DESCRIBING INFORMATION

Representation: Prothiaden is Dothiepin Hydrochloride B.P., an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal adult dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £3.73. **Product Licence Numbers:** PL0014/5941, PL0014/0209. © The Boots Company PLC, Nottingham, England. Further information available on request.

cis(Z)-flupenthixol decanoate

D I F F E R E N C E

= Proven antipsychotic effect⁽¹⁻⁷⁾

↑ Restores mood⁽¹⁻³⁾

~ Dosage flexibility

< Cost-effective therapy⁽⁸⁾

PRESCRIBING INFORMATION

Depixol Injection and Depixol-Conc. Injection contains cis(Z)-flupenthixol decanoate, 20mg per ml and 100mg per ml respectively, in thin vegetable oil.

Indications Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy.

Dosage and Administration By deep intramuscular injection, 1-2ml every 2-4 weeks, to a maximum of 400 mg weekly. Children: Not recommended for children.

Side Effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson drug treatment.

Contra-indications Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusional, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy.

Further Information Overdosage should be treated;

(a) by anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur, (b) by sedation (with benzodiazepines) in the unlikely event of agitation or excitement, (c) by noradrenaline in saline intravenous drip if the patient is shocked.

Package Quantities & Basic NHS Prices Boxes of 10 x 20mg (1ml) £15.53, 10 x 40mg (2ml) £25.99, 10 x 100mg (1ml) ampoules £59.53, 5 x 20mg and 5 x 40mg syringes £8.51 and £13.74, 1 x 200mg (10ml) and 1 x 500mg (5ml) vials £14.74 and £28.27.

axes visually and with regard to their own posture when vision is obscured (Proctor *et al*, 1964; Danta & Hilton, 1975). Gainotti *et al* (1980) compared patients with Parkinson's disease, Huntington's disease, and Alzheimer's disease and found the latter to be significantly more impaired on tests requiring copying of designs. In another study comparing patients with cortical and subcortical dementias, Brouwers *et al* (1984) demonstrated that Alzheimer's disease patients had more difficulty with reproduction of constructional models, whereas Huntington's disease patients had greater impairment on a road map test. Kimura *et al* (1981) found that patients with PSP manifest abnormalities on tasks involving visual search or visual scanning abilities.

Cognition

Patients with Parkinson's disease also suffer from a variety of cognitive deficits. Category naming (verbal fluency, number of members of a specified category named in one minute) is diminished in many parkinsonian patients (Matison *et al*, 1982; Lees & Smith, 1983). They may also exhibit abnormalities on the similarities subtest of the Wechsler Adult Intelligence Scale (WAIS) and have difficulty shifting set on tasks requiring abstraction and categorisation (Talland & Schwab, 1964; Reitan & Ball, 1971; Lees & Smith, 1983; Globus *et al*, 1985). The latter deficit is partially reversible with levodopa therapy, supporting a relation with the underlying dopamine deficiency (Bowen *et al*, 1975).

Huntington's disease patients exhibit a similar pattern of cognitive deficits. Category naming is impaired early in the course of the disease, and subtests of the WAIS dependent on abstraction and concept manipulation are performed poorly (Boll *et al*, 1974; Butters *et al*, 1978; Josiassen *et al*, 1982).

The cognitive deficits of PSP similarly include poor abstraction, difficulty shifting sets, and poor manipulation of information (Rafal & Grimm, 1981; Maher *et al*, 1985). The cognitive deficits of the spinocerebellar degenerations have not been well studied but appear to resemble those of other subcortical dementias and lack the features indicative of cortical dysfunction (Carter & Sukavajana, 1956; Chandler & Debin, 1956; Cummings & Benson, 1983; Trauner, 1985). Similarly, the cognitive abnormalities of idiopathic basal ganglia calcification and Wilson's disease share the characteristics of subcortical dementia (Knehr & Bearn, 1956; Cummings *et al*, 1983).

Language

Compared with other areas of neuropsychological function, language is largely spared in the subcortical dementias. In Parkinson's disease, Huntington's disease, and PSP patients perform normally or manifest mild deficits in picture and object naming, but they lack the more severe disturbances of comprehension and the paraphasic abnormalities characteristic of the cortical dementias (Butters *et al*, 1978; Matison *et al*, 1982; Bayles & Tomoeda, 1983; Cummings *et al*, 1985; Globus *et al*, 1985; Maher *et al*, 1985). The few studies of Wilson's disease reveal relative preservation of vocabulary, whereas abstraction and conceptualisation abilities are compromised (Knehr & Bearn, 1956; Goldstein *et al*, 1968).

Summary and contrast with cortical dementias

Analysis of the neuropsychological profile of subcortical dementia allows the pattern of intellectual disturbances to be contrasted with the abnormalities manifested by patients with dementias involving predominantly the cerebral cortex (Table I). Subcortical dementias are characterized by psychomotor retardation, whereas the cortical dementias manifest normal psychomotor speed throughout most of the clinical course (Cummings & Benson, 1986). Memory disturbances are present in both cortical and subcortical dementias, but subcortical disorders have a prominent recall deficits and are benefited by clues and recognition tasks whereas the memory abnormalities in cortical dementias are a product of encoding failure and are aided little by recall facilitation strategies. Language abnormalities provide the most readily observable distinctions between cortical and subcortical dementias: subcortical conditions manifest no abnormalities or have mild impairments of confrontation naming and auditory comprehension, whereas cortical dementias evidence fluent paraphasic verbal output with severe anomia and moderate to severely impaired language comprehension (Cummings & Benson, 1983; Cummings *et al*, 1985). Visuospatial abilities are abnormal in both cortical and subcortical dementias. Alzheimer's disease patients have greater difficulty performing constructional tasks, and patients with subcortical dementias are more impaired on tests involving egocentric spatial operations such as map reading and judgement of vertical and horizontal axes (Proctor *et al*, 1964; Danta & Hilton, 1975; Boller *et al*, 1984; Brouwers *et al*, 1984). Abnormalities of abstraction and categorisation are present in both cortical and subcortical dementias

TABLE I
Contrasting features of cortical and subcortical dementias

<i>Characteristics</i>	<i>Subcortical dementia</i>	<i>Cortical dementia</i>
Neuropsychological features		
Severity	Mild to moderate throughout most of the course	More severe deficits earlier in the disease course
Speed of cognition	Slowed	Normal
Memory		
Short term	Recall partially facilitated by clues and recognition tasks	Encoding deficit; aided little by clues
Remote recall	No temporal gradient	In early stages, temporal gradient may be present
Language	Normal or mild anomia	Anomia, comprehension deficit, paraphasia
Visuospatial skills	Impaired; poor manipulation of egocentric space (map reading, judgement of horizontal and vertical)	Impaired; poor model copying
Cognition	Poor abstraction and categorization	Impaired early; late untestable
Neuropsychiatric features		
Personality	Apathy, irritability	Indifference, occasional disinhibition
Depression	Common	Uncommon
Mania	Infrequent	Absent
Psychosis	Common in some disorders, may have complex delusions	Common; simple delusions
Motor system		
Speech	Dysarthria	No dysarthria
Posture	Flexed or extended	Normal (flexed late)
Gait	Hypokinetic or hyperkinetic	Normal (until late)
Speed	Slow	Normal (until late)
Adventitious movements	Tremor, chorea, dystonia	None or myoclonus
Tone	Abnormal (hypotonic in choreic disorders; hypertonia in parkinsonian conditions)	Normal early; rigid or gegenhalten in later stages
Topography of pathologic changes	Most intense changes in striatum and thalamus	Frontal and temporo-parieto-occipital association cortex and hippocampus most involved
Neurochemical changes	<i>Huntington's disease:</i> decreased GABA, angiotensin converting enzyme, substance P, cholecystokinin-like immunoreactivity, and CAT <i>Parkinson's disease:</i> decreased dopamine, noradrenalin, serotonin, methionine-enkephalin, CAT, neurotensin, bombesin, cholecystokinin-immunoreactivity, GABA <i>PSP:</i> decreased dopamine, variable loss of CAT	<i>Alzheimer's disease:</i> decreased CAT, somatostatin, and norepinephrine
Aetiologic disorders	Degenerative extrapyramidal syndromes, subcortical infarctions; subcortical infectious, metabolic, and neoplastic conditions	Alzheimer's disease, Pick's disease

but are more severe in the former. Thus, psychomotor retardation is most characteristic of subcortical dementias and aphasia is most indicative of a cortical dementing disease; other neuropsychological abilities are affected by both cortical and subcortical conditions, but their effects within these domains are often qualitatively distinguishable.

Detection and characterisation of the subcortical dementias depends on utilising techniques sensitive to the intellectual consequences of subcortical dysfunction. Previous failures to establish differences between cortical and subcortical dementia utilised simple mental status questionnaires insensitive to the distinguishing features of the different patterns of intellectual deterioration (Mayeux *et al*, 1983). Future investigations of the intellectual deficits of subcortical dementias should focus on the differences between individual subcortical disorders (e.g. Parkinson's disease vs Huntington's disease), the relationships among the individual components of the dementia syndromes (e.g. association of the memory, visuospatial, and cognitive abnormalities), and comparative studies of cortical and subcortical dementias.

Neuropsychiatric aspects

In addition to intellectual impairments, abnormalities of personality, mood, and reality testing are common in the subcortical dementias. Like the intellectual disturbances, the neuropsychiatric alterations are products of the subcortical anatomic and biochemical changes, providing insight into the contributions of these regions to motivation, mood, and emotional function (Cummings, 1985a).

Personality alterations

Wilson (1912) called attention to the personality alterations associated with hepatolenticular degeneration when he observed that the patients appeared "docile" and "childish". Albert *et al* (1974) noted that patients with PSP were apathetic or irritable and had brief outbursts of rage. Similar changes have been observed in patients with idiopathic Parkinson's disease. Patients are less involved in family and social affairs, initiate fewer interpersonal interactions, and are more content with inactivity. Minnesota Multiphasic Personality Inventory (MMPI) profiles of Parkinson's disease patients have shown elevations on scales indicative of depression, hypochondriasis, and schizophrenia-like thought (Beardsley & Puletti, 1971; Hoehn *et al*, 1976).

The behaviour of Huntington's disease patients is

characterised by apathy, inertia, hostility, and irritability (Rosenbaum, 1941; Goodman *et al*, 1966; McHugh & Folstein, 1975; Mayeux, 1983). Caine & Shoulson (1983) studied 30 patients with Huntington's disease and found that 22 were apathetic and 11 lacked insight into the nature and consequences of their disability. Chronic dysthymia, anxiety, and intermittent explosive disorder were also observed. They noted that apathy and loss of insight were more frequent among patients in the more advanced stages of the illness. Dewhurst *et al* (1969) investigated 102 patients with Huntington's disease and found that, among the 68 patients for whom behavioural information was available, 44 suffered from anxiety or personality alterations in the prodromal period, and the frequency of neuropsychiatric alterations increased as the disease progressed. Thus, apathy and inertia are common features of subcortical disorders and a variety of conduct and personality changes have also been reported. Few quantitative studies of this aspect of behaviour have been undertaken, and there has been little attempt to establish correlations between the presence and degree of intellectual impairment and the behavioural alterations.

Depression

Depression has received the most systematic study of all non-cognitive alterations in subcortical disorders and was recognised by Albert *et al* (1974) and McHugh & Folstein (1975) to be a cardinal feature of subcortical dementia.

Some degree of depression has been identified in 37–89% of patients with idiopathic Parkinson's disease (Mindham, 1970; Brown & Wilson, 1972; Ceesia & Wanamaker, 1972; Robins, 1976; Horn, 1974; Mayeux *et al*, 1981). Moderate to severe depression occurs in 35–50% of Parkinson's disease patients, and depression is significantly more common than among patients with other types of neurological disorders or comparably disabling medical conditions. The depression correlates imperfectly with the degree of motor impairment, suggesting that it is not merely a reaction to physical disability but is biologically linked to the underlying neuropathological changes. Depression is reported to occur more frequently among patients with intellectual impairment than among those without evidence of dementia (Mayeux *et al*, 1981, 1983).

Depression is also common in patients with Huntington's disease. Dewhurst *et al* (1969) reported that of 102 patients 42 were depressed, and Caine & Shoulson (1983) found that six of 24 patients had major depressive episodes, with an additional six

suffering from dysthymic syndromes. Schoenfeld *et al* (1984) noted that suicide is approximately four times more common among patients with Huntington's disease than among the general population, and is eight times greater in the 50–69 year-old age group.

Depression has also been observed among patients with PSP, subcortical infarctions, Wilson's disease, and spinocerebellar degenerations but prevalence studies are not available (Davies, 1949; Albert *et al*, 1974; Trimble & Cummings, 1981; Jackson *et al*, 1983; Janati & Apple, 1984; Cummings 1985a,c). In contrast, severe depression is uncommon in cortical degenerative processes such as Alzheimer's disease (Cummings & Benson, 1986).

Mania

Mania is less common than other neuropsychiatric conditions associated with subcortical disorders but occurs too frequently to be considered a chance association. McHugh & Folstein (1975) reported that two of eight patients with Huntington's disease had manic episodes. Dewhurst *et al* (1969) found that of 102 patients with Huntington's disease, 14 were euphoric, two had hypomania, and five had grandiose delusions.

Mania has also been observed in Wilson's disease and post-encephalitic Parkinson's disease (Fairweather, 1947; Pandey *et al*, 1981), and Cummings & Mendez (1984) drew attention to the fact that a majority of focal lesions producing secondary mania are located subcortically in hypothalamic and perithalamic regions.

Psychosis

Psychosis manifested by the endorsement of delusional beliefs is closely correlated with subcortical dysfunction and has been observed with unusual frequency among patients with Huntington's disease, post-encephalitic Parkinson's disease, Wilson's disease, idiopathic basal ganglia calcification, and spinocerebellar degenerations, as well as subcortical vascular, traumatic, and neoplastic lesions (Cummings, 1985a,c). The psychosis may precede the dementia or may occur concomitantly with it. In the series of Huntington's disease patients reported by Dewhurst *et al* (1969), 50% had delusions at the time of admission to hospital. Six of 30 Huntington's disease patients reported by Caine & Shoulson (1983) had schizophrenia-like, paranoid, or atypical psychoses. Of 46 patients reviewed by Rosenbaum (1941), 38 were delusional for some period during the course of this illness.

Thus, when the entire course of the disease is taken into account, it appears that a majority of patients with Huntington's disease will manifest psychotic ideation.

Psychosis is uncommon in idiopathic parkinsonism except when induced by anticholinergic or dopaminergic agents but was reported in 17–57% of patients with post-encephalitic Parkinson's disease (Fairweather, 1947; Mindham, 1970; Celesia & Wanamaker, 1972; Crow *et al*, 1976). Likewise, approximately 50% of all reported patients with idiopathic basal ganglia calcification have a schizophrenia-like psychosis (Cummings *et al*, 1983), and psychosis has also been reported among patients with Wilson's disease, spinocerebellar degenerations, and subcortical neoplasms and infarctions (Jackson & Immerman, 1919; Davies, 1949; Shepherd, 1955; Malamud, 1967; Keddies, 1969; Trimble & Cummings, 1981; Cummings 1985b,c). Cummings (1985b), in a comparative study of delusions in a variety of neurological disorders, found that patients with cortical dementing illnesses (Alzheimer's disease) had more severe dementias and manifested simple paranoid misbeliefs, whereas patients with subcortical dementias had less severe intellectual alterations and tended to have complex, highly structured delusions.

Pathology and pathophysiology

Correlations between the phenomenology of subcortical dementia and the anatomic structures and biochemical systems involved have not been fully established, but preliminary information derived from pathoanatomic investigations allow a tentative formulation of the structural and biochemical alterations involved in these conditions.

Histopathologic alterations

The pathological anatomy of the extrapyramidal syndromes is well established. In Huntington's disease, the greatest pathological alterations involve the caudate nuclei where Golgi type II interneurons are preferentially lost. The putamen and thalamus manifest less severe alterations (Corseillis, 1976; Dom *et al*, 1976; Cummings & Benson, 1983).

Lewy bodies and neuronal loss are the histopathologic alterations characteristic of idiopathic Parkinson's disease. The changes are most intense in the substantia nigra, ventral tegmental area, and locus coeruleus; less intense or variable alterations occur in the nucleus basalis, caudate, putamen, globus pallidus, and cerebral cortex (Greenfield &

Bosanquet, 1953; Den Hartog Jager & Bethlem, 1960; Oppenheimer, 1976; Javoy-Agid & Agid, 1980; Whitehouse *et al.*, 1983).

Progressive supranuclear palsy has its greatest impact on the structures of the mesencephalic-diencephalic junction including the red nuclei, subthalamic nuclei, globus pallidus, thalamus, substantia nigra, and cerebellar nuclei (Steele *et al.*, 1969). In Wilson's disease, the putamen is most involved, and the caudate, subthalamic nuclei, red nuclei, and thalamus show less intense alterations (Wilson, 1912; Smith, 1976). The pathologic geography of the spinocerebellar degenerations is variable but routinely includes the cerebellum and brainstem, and in many cases alterations are detectable in the basal ganglia, substantia nigra, and thalamus (Greenfield, 1954; Oppenheimer, 1976). Patients with idiopathic calcification of the basal ganglia have dense perivascular calcific deposits in the caudate, putamen, globus pallidus, and cerebellar nuclei (Oppenheimer, 1976; Cummings *et al.*, 1983). Thalamic degeneration involves primarily the anterior and dorsal thalamic nuclei with variable involvement of putamen, cerebral white matter, cerebral cortex, and inferior olives (Stern, 1939; Schulman, 1957; Katz *et al.*, 1984). A similar distribution of lesions was present in one case of post-herpetic thalamic dementia (Pilleri *et al.*, 1981); whereas one patient with sarcoid-related subcortical dementia had prominent granuloma formation in the hypothalamus, fornix, and infundibulum (Hier *et al.*, 1983). Multi-infarct syndromes with subcortical dementia have had lesions concentrated in the basal ganglia and thalamus (Cummings & Benson, 1983; Graff-Radford *et al.*, 1984; Guberman & Stuss, 1983). In summary, the disorders reported to produce subcortical dementia routinely involve the striatal nuclei and/or thalamus with more variable involvement of subthalamic nuclei, substantia nigra, red nuclei, locus coeruleus, cerebellar nuclei, and cerebral cortex (Benson & Cummings, 1985).

The extent and nature of cortical involvement associated with dementia in Parkinson's disease is controversial. Hakim & Mathieson (1979) and Boller *et al.* (1980) found an increased number of senile plaques and neurofibrillary tangles in the cerebral cortex of demented Parkinson's disease patients and suggested that the dementia was secondary to co-occurring Alzheimer's disease. Ball (1984), however, found no increase in Alzheimer-type pathology among Parkinson's disease patients with dementia, and epidemiological studies suggest that the two diseases co-occur no more frequently than predicted by chance in an elderly population (Heston *et al.*,

1981). As outlined above, the nature of the neuropsychological alterations occurring in most patients with Parkinson's disease are unlike those noted in Alzheimer's disease. Progress towards the resolution of these discrepancies depends on thorough documentation of neuropsychological deficits in Parkinson's patients and correlation with quantitative analysis of cortical and subcortical pathologic and neurochemical changes.

Investigations of the anatomical foundations of dementia have emphasised the possible role of the nucleus basalis of Meynert (NBM). Whitehouse *et al.* (1981) documented atrophy of the NBM in Alzheimer's disease and suggested that loss of these cholinergic neurons and their cortical projections could account for the cholinergic deficit and the dementia of Alzheimer's disease. Later, Whitehouse *et al.* (1983) demonstrated that NBM is also atrophic in Parkinson's disease patients with dementia and suggested that the two types of dementia might have a similar pathophysiology. More recent studies show that NBM cell loss occurs in a number of neurological illnesses including Parkinson's disease patients that lack neuropathological features of Alzheimer's disease, Wernicke-Korsakoff syndrome, and PSP (Arendt *et al.*, 1983; Nakano & Hirano, 1984; Tagliavini *et al.*, 1984). These observations suggest that atrophy of NBM is a feature common to several dementing disorders, occurs in diseases with and without Alzheimer-type neuropathological changes, and has been identified in disorders with a variety of types of neurobehavioural alterations. Atrophy of NBM cannot as yet be correlated with any specific neuropsychological or neuropsychiatric syndrome. No atrophic changes are found in NBM in Huntington's disease or in post-encephalitic parkinsonism (Clark *et al.*, 1983; Whitehouse *et al.*, 1983).

Biochemical alterations

Intellectual ability is no less a product of the activity of neurotransmitter systems than of neuroanatomical structures. In some cases the effects of structural alterations may be mediated through changes in transmitter function; in others, the biochemical alterations and resultant mental status deficits may occur in the absence of overt anatomical pathology. Consideration of the consequences of loss of neurotransmitter function is particularly important in subcortical disorders because several major transmitter systems (e.g., dopamine, norepinephrine, acetylcholine, serotonin) have their cells of origin in subcortical nuclei and project via subcortical tracts to diencephalic and telencephalic regions (Anden *et al.*, 1966; Mesulam, 1983).

In Huntington's disease the principal abnormality is a 50–90% reduction in γ -aminobutyric acid (GABA) and related enzymes in the striatum (Perry *et al*, 1973; Bird & Iversen, 1974). Substantial reductions have also been found in angiotensin converting enzyme, substance P, methionine-enkephalin, and cholecystokinin-like immunoreactivity (McGeer & McGeer, 1976; Arregui *et al*, 1977; Emson *et al*, 1980a; Emson *et al*, 1980b). Choline acetyltransferase (CAT) is variably reduced and other enzymes associated with metabolism of acetylcholine and of catecholamines are normal (Perry *et al*, 1973; Bird & Iversen, 1974; McGeer & McGeer, 1976). The neurotransmitter and neuromodulator deficits are confined to subcortical structures; cortical enzyme activities are normal. Likewise, neurotransmitter receptor studies have shown decreased muscarinic cholinergic and GABA binding in neostriatum, increased pallidal GABA binding, and normal cortical receptor function (Enna *et al*, 1976; Wastek & Yamamura, 1978; Penny & Young, 1982; Whitehouse *et al*, 1985). Thus, in Huntington's disease there is a preferential loss of GABA and a number of neuromodulators and related enzymes from subcortical structures, whereas neurochemical analyses of cerebral cortex (including the frontal lobe) reveal no abnormalities.

In idiopathic Parkinson's disease, the type and distribution of neurotransmitter alterations have been extensively studied. The most prominent and consistent abnormalities involve the dopaminergic system including dopamine, homovanillic acid, tyrosine hydroxylase, and dopadecarboxylase (Hornykiewicz, 1973). The dopamine losses are not confined to the basal ganglia but involve the midbrain ventral tegmental area, hypothalamus, and limbic structures as well (Price *et al*, 1978; Javoy-Agid *et al*, 1981, 1984). Less pronounced losses of dopamine and related metabolites have also been identified in the cerebral cortex (Scatton, 1982). Noradrenalin, serotonin, methionine-enkephalin, neurotensin, bombesin, and cholecystokinin immunoreactivity are also reduced in subcortical structures (Studler *et al*, 1982; Taquet *et al*, 1982; Scatton *et al*, 1983; Bissette *et al*, 1985). GABA and related enzymes have been found to be reduced in most but not all studies of patients with Parkinson's disease. Efforts to relate neurobehavioural alterations to these chemical changes have revealed significant correlations between impaired intellectual performance and decrease norepinephrine metabolites in the CSF (Mann *et al*, 1983; Stern *et al*, 1984); neuropsychological abnormalities also correlate with increased CSF homovanillic acid and acetylcholinesterase levels (Direnfeld *et al*, 1984); and

depression is associated with decreased CSF 5-hydroxyindoleacetic acid, the principal metabolite of serotonin (Mayeux *et al*, 1984). A correlation has also been found between severity of dementia and reduction of neurotensin in the putamen as measured at autopsy (Bissette *et al*, 1985). Studies of cholinergic system enzymes have raised several questions. Some investigators found no difference in cholinergic enzyme levels between parkinsonian and control subjects (McGeer & McGeer, 1971, 1976; Lloyd *et al*, 1975). Perry and colleagues (1983) however, found reduced levels of CAT in the cortex of demented Parkinson's disease patients. The latter cases also had widespread senile plaques and neurofibrillary tangles and may have been suffering from dementia of the Alzheimer type. Similarly, Ruberg *et al* (1982) and Epelbaum *et al* (1983) found that demented Parkinson's disease patients had decreased cortical acetylcholinesterase, but these patients also had Alzheimer-type histopathology and low somatostatin levels characteristic of Alzheimer's disease. Such observations along with the histologic studies described above, suggest that a number of patients with Parkinson's disease have dementia of the Alzheimer type with typical Alzheimer-type histopathology and chemopathology, other groups have cortical cholinergic deficits without Alzheimer-type histopathological changes, or more restricted subcortical, pathological and neurochemical alterations (Gaspar & Gray, 1984). The frequency with which dementia syndromes are noted in Parkinson's disease patients and the differences between the neuropsychological deficits of Parkinson's disease and Alzheimer's disease suggest that dementia is not confined to parkinsonians with cortical abnormalities, although Alzheimer's disease may account for a majority of severe dementias occurring among parkinsonian patients.

The serendipitous discovery that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a synthetic analogue of meperidine, produces the rapid onset of an irreversible form of parkinsonism has provided new insights into the biochemical basis of subcortical dementia (Ballard *et al*, 1985): MPTP produces a nearly pure hypodopaminergic state by selective destruction of dopaminergic neurons in the substantia nigra (Davis *et al*, 1979; Burns *et al*, 1983). Neuropsychological assessment of patients with MPTP-induced Parkinson's disease patients reveals abnormalities of attention and cognition consistent with subcortical dementia (Stern & Langston, 1985). These observations indicate that a pure dopamine deficiency is sufficient to produce subcortical dementia.

TABLE II
Characteristics of instrumental and fundamental functions

<i>Characteristics</i>	<i>Instrumental functions</i>	<i>Fundamental functions</i>
Neuropsychological activities	Language, memory, perceptual recognition, praxis, calculation	Timing, arousal, attention, motor programming, motivation, mood
Neuropsychological deficits	Aphasia, amnesia, agnosia, apraxia, acalculia	Slowing, forgetfulness, dilapidation of cognition, depression, apathy
Associated type of dementia	Cortical	Subcortical
Principal grey matter structures	Multi-layered cortex (neopallial association cortex and hippocampus)	Deep nuclei (basal ganglia, thalamus, rostral brainstem)
White matter connections	Discrete well myelinated intra- and interhemispheric tracts	More diffuse, shorter, less well myelinated projections
Organisational composition	Parallel connection of functional units; lateral dominance well developed	Serial connection of structures with overlapping functions; poorly lateralised
Phylogeny	Recent evolutionary acquisition, most well developed in humans	More primitive, present in triune structure of reptile brain
Ontogeny	Incompletely developed at birth, myelination and dendritic growth continue through childhood	Functional at birth or soon after
Major neurotransmitters	Acetylcholine	Dopamine, norepinephrine, serotonin, GABA, acetylcholine

Recently, the biochemical disturbances associated with PSP have been identified. There is a marked nigrostriatal dopamine deficiency with preserved mesocortical and mesolimbic dopamine levels (Kish *et al*, 1985; Ruberg *et al*, 1985). Ruberg and colleagues (1985) found 50% reductions of CAT in subcortical structures and a 20% reduction in the frontal cortex, whereas Kish *et al* (1985) found no CAT deficiencies even in two patients with severe dementia. Noradrenalin, serotonin, GABA, and aspartic acid levels were normal (Kish *et al*, 1985). Thus, PSP and its concomitant dementia correlate best with reduced dopamine levels and show little relation to cortical cholinergic system deficits.

Other subcortical disorders have not been adequately characterised neurochemically, but sufficient information is available to suggest that hypokinetic-rigid syndromes predictably reflect striatal dopamine deficiency (Hornykiewicz, 1973), and the dementias accompanying these disorders can be attributed to the dopamine loss (Bachman & Albert, 1984).

Metabolic investigations

Recent investigations using positron emission tomography (PET) and cerebral blood flow (CBF)

techniques have added a new dimension to understanding the pathophysiology of subcortical dementia. Studies of Huntington's disease patients using PET reveal a distinctive pattern of metabolism characterised by decreased activity of caudate and putamen and normal cerebral metabolism (Kuhl *et al*, 1982). This pattern correlates well with the pathological and neurochemical findings in identifying impaired subcortical function and preserved cortical function. It contrasts with the cortical hypometabolism and relatively intact metabolic function of subcortical regions observed in Alzheimer's disease (Benson *et al*, 1983; Foster *et al*, 1984).

Studies of hemiparkinsonism with PET reveal decreased metabolism in the putamen and globus pallidus contralateral to the parkinsonian manifestations (Garnett *et al*, 1984; Martin *et al*, 1984). Studying bilateral parkinsonism, Kuhl *et al* (1984) found a generalised decrease in brain metabolism involving cortical and subcortical structures. Five of these patients were restudied 3-4 years later: one with severe dementia exhibited a PET pattern characteristic of Alzheimer's disease, three of the remaining patients had more modest dementias and showed an 18-40% decrease in cortical metabolic activity in a pattern unlike that of Alzheimer's disease. Cerebral cortical blood flow is also decreased

in Parkinson's disease, but the magnitude of CBF reduction shows no correlation with the presence or severity of intellectual deterioration (Lavy *et al.*, 1979; Bes *et al.*, 1983; Globus *et al.*, 1985). This lack of association suggests that the two functions are separately mediated, with subcortical dysfunction (not reflected in CBF studies) accounting for much of the dementia. Positron emission tomography studies in PSP have demonstrated diminished metabolism in the frontal lobes (D'Antona *et al.*, 1985). Metabolic studies of other subcortical disorders with dementia are not yet available; when completed and correlated with the type and extent of neuropsychological abnormality, such investigations should broaden understanding of the physiology of subcortical dysfunction and its intellectual consequences.

Mechanisms of subcortical dementia

Investigations of the neuropsychology, anatomy, and biochemistry of subcortical disorders have provided sufficient information on which to base a tentative explanation of how subcortical dysfunction results in a dementia syndrome. Subcortical structures are not merely relay nuclei linking the cerebral cortex with brainstem and spinal cord; rather they have important analytic and synthetic functions that modify, focus, and direct incoming and outgoing impulses. The thalamus mediates sensory, cognitive, and limbic activities through specific thalamocortical circuits and establishes cortical arousal through non-specific reticulothalamocortical projections (Walker, 1937; Jasper, 1949; Krieg, 1966). Arousal, activation, and attention are dependent on the integrity of these connections. The striatal nuclei receive afferents from all cerebral cortical areas, and there are particularly dense connections between the frontal lobe cortex and the caudate nucleus (Kemp & Powell, 1970; Graybiel & Ragsdale, 1979). These projections provide an anatomic basis for the similarities between subcortical dementias and of frontal lobe syndromes such as perseveration, impersistence, distractibility, difficulty shifting sets, abnormal verbal fluency, poor abstraction, impaired categorisation, and difficulty with strategy generation and problem solving (Johnson *et al.*, 1968). Terms such as 'frontal systems disorder', 'frontal-subcortical systems disorder', or 'frontal-subcortical dementia' are acceptable alternatives to 'subcortical dementia' and might more accurately reflect the realm of anatomic, metabolic, and neurochemical dysfunction found in this group of conditions.

Important links have also been discovered between the basal ganglia and the limbic system. Limbic

structures have largely unreciprocated projections to nearly all parts of the striatum creating a limbic-striatal system that utilises dopamine as an important neurotransmitter (Nauta & Domesick, 1978, 1981; Nauta, 1982; Iversen, 1984). These connections subserve motivation, mood, and aspects of reality testing, and disturbances of such functions contribute to the apathy, mood abnormalities, and psychoses observed in subcortical disorders.

Conceptually, cortical and subcortical abilities can be categorised as instrumental functions and fundamental functions, respectively (Table II) (Albert, 1978). Instrumental functions include language, praxis, perceptual recognition, memory, and calculation. These faculties depend on the integrity of focal cortical regions and are subject to interruption by localised cortical lesions or by disconnection of relevant cortical-to-cortical white matter tracts. Abnormalities of instrumental functions produce aphasia, apraxia, agnosia, amnesia, and acalculia—deficits associated with the cortical dementias. Available neuropsychological instruments are most sensitive to detection of these cortical disturbances. Instrumental abilities are the most highly evolved of human activities and depend on phylogenetically recent and ontogenetically late developing structures (Yakovlev, 1948). Organisationally, instrumental abilities involve discrete cortical areas with specialised functions connected by well myelinated intra- and interhemispheric white matter tracts. Acetylcholine plays an essential role in cortical neurotransmission.

Fundamental functions, on the other hand, include arousal, activation, attention, sequencing, motivation, and mood. These functions are much less discretely organised and involve subcortical nuclei (basal ganglia and thalamus) that interconnect widely with the cerebral cortex. The major projections are reciprocal connections with the frontal lobe and afferent connections from the limbic system. Organisationally, subcortical nuclei are connected by shorter white matter projections, which are not so well myelinated (Yakovlev, 1948). A variety of neurotransmitters are utilised including dopamine, serotonin, noradrenalin, GABA, acetylcholine, and others. Fundamental functions are crucial to survival and emerge early in phylogenetic and ontogenetic development. Dysfunction of these fundamental abilities produces the cardinal features of subcortical dementia including slowed information processing, dilapidation of memory and cognition, and disturbances of mood and motivation. Direct neuropsychological assessment of fundamental functions is difficult, and subcortical dysfunction must often be inferred from the

behaviour of the patient and the pattern of effects on the more accessible instrumental abilities. The movement abnormalities that frequently accompany the subcortical dementias (rigidity, chorea, athetosis, dystonia, bradykinesia) are not coincidental but reflect the dependence of the extrapyramidal motor system on anatomic structures, neurotransmitters, and neurophysiological activities that also mediate fundamental functions.

Further investigation is needed to refine, modify, and extend the concept of subcortical dementia. Sufficient information is available, however, to demonstrate that subcortical dementia is characterised by a clinical syndrome that is identifiable and can be distinguished from the syndrome of cortical dementia. The clinical features of subcortical dementia correlate with dysfunction of striatum and thalamus and of specific neurotransmitter systems. The characteristics of subcortical dementia reflect disruption of fundamental functions associated with a phylogenetically and ontogenetically less advanced level of neurological organisation. Fundamental functions are essential components of human mental abilities, and their compromise has grievous consequences for human thought and emotion.

CAMDEX

A Standardised Instrument for the Diagnosis of Mental Disorder in the Elderly with Special Reference to the Early Detection of Dementia

M. ROTH, E. TYM, C. Q. MOUNTJOY, F. A. HUPPERT, H. HENDRIE, S. VERMA and R. GODDARD

A new interview schedule for the diagnosis and measurement of dementia in the elderly is described. The schedule named the Cambridge Mental Disorders of the Elderly Examination (CAMDEX), consists of three main sections: (1) A structured clinical interview with the patient to obtain systematic information about the present state, past history and family history; (2) a range of objective cognitive tests which constitute a mini-neuropsychological battery; (3) a structured interview with a relative or other informant to obtain independent information about the respondent's present state, past history and family history. The CAMDEX is acceptable to patients, has a high inter-rater reliability and the cognitive section has been shown to have high sensitivity and specificity.

Introduction

Attempts have been made in the past to assess and characterise patients suffering from dementia in late and middle life. They have aimed at resolving three related, but relatively distinct, problems:

- (1) To diagnose dementias reliably either by the use of operational criteria such as those set down in DSM-III (American Psychiatric Association 1980) or by using standardised methods of interview and examination such as the Present State Examination (PSE) of Wing *et al* (1974) or its derivatives.
- (2) To develop valid and reliable measures of the severity and extent of cognitive impairment which constitutes a central feature in established cases of dementia.
- (3) To devise reliable means of rating behaviour and adaptation in everyday life that are as objective and precise as the situation permits and independent of clinical diagnosis or severity of dementia as judged from performance on standardised tests.

As a result of these enquiries, a number of scales useful for certain specific purposes have been developed. For example, standardised diagnostic interviews such as the Psychogeriatric Assessment Schedule (PAS) of Bergmann *et al* (1975) are capable of separating groups of patients into 'demented' and 'non-demented' or 'functional' groups. This makes them valuable for certain kinds of scientific enquiry: for example, clinical trials or epidemiological studies

in the community to provide a basis for social and health care planning. A large number of cognitive tests have come into existence which are of two broad types. Mental state examinations are capable of differentiating between the presence or absence of significant cognitive impairment while tests which derive from the psychometric tradition such as the Kendrick Battery (Kendrick, 1972; Kendrick & Moyes, 1979) permit an assessment of severity of cognitive impairment. There are also many useful behaviour rating scales which can detect problems in the activities of daily living. One of these scales, the widely used Dementia Scale of Blessed *et al* (1968) shows a good correlation with Alzheimer neuropathology, while the rating scale of Roberts & Caird (1976) has been found to correlate with computed tomography (CT) scans.

However, one source of difficulty and confusion has been the failure to differentiate between the type of information which each of these three approaches can validly yield. In consequence, a scale or interview developed to answer one type of question has been inappropriately used to answer another. For example, behavioural scales alone have been employed as measures of dementia or the results of cognitive tests have been used to establish a diagnosis. Such misconceptions are liable to introduce error and confusion, into research endeavours and clinical practice alike.

We believe that the three approaches to characterising the demented patient are complementary. All three are required to obtain a

complete picture of the disorder. The central objective of the endeavour to be described in this paper was to incorporate these different kinds of measure within a single compact, integrated instrument that has an acceptable measure of reliability and validity.

Developments in the diagnosis of dementia

Although operational criteria for the diagnosis of dementia such as those provided in DSM-III have improved stringency in diagnostic practice, they are somewhat arbitrary. Moreover, these criteria do not serve to identify mild dementia which presents a problem of central importance in this field (Henderson & Huppert, 1984).

There is more promise in the structured and semi-structured interview schedule from which diagnosis of organic mental disorder can be derived. The two best known schedules are the Present State Examination (PSE) of Wing *et al* (1974) and the Diagnostic Interview Schedule (DIS) of Robins *et al* (1981). However, neither of these instruments provide sufficient information regarding the history of onset and the character and progression of cognitive impairment.

The Geriatric Mental State Examination (GMS) of Copeland *et al* (1976) which is largely derived from the PSE and uses the same hierarchical approach to the problem of diagnosis, incorporates more tests of cognitive function. It has been used in the influential US-UK Diagnostic Project for comparing mental disorder in the elderly in New York and London and has now been incorporated, with some modification, into the Comprehensive Assessment and Referral Evaluation (CARE) of Gurland *et al* (1977). It differentiates between six principal diagnostic categories of old age mental disorder. They are: affective disorders, schizophrenia/paranoid states, organic psychoses, alcoholism, neuroses and personality disorders, and other diagnoses. And in two small studies of inter-rater reliability (Copeland *et al*, 1976), the diagnostic agreement was of the order of 85% on a sample of 20 and 73% on a sample of 22 patients.

These scales represent an advance in that they standardise the examination of the present mental state and render the findings relating to the present state more objective and replicable. However, the entire psychiatric examination required to make a diagnosis has not been standardised.

This is of particular importance in the characterisation and measurement of dementia. The relevant data cannot be extracted from standardised examinations formed on the present mental state alone. Such

findings can lead to error if they are not combined with data relating to the development of the disorder. Information regarding adaptation during development and basic personality traits and observations on the behaviour of the patient over a period of time are also needed to determine the extent of his pre-morbid traits and competence in negotiating everyday tasks. For such information, the judgments of a relative or friend or observations conducted over a period in hospital, are indispensable. Such behaviour will sometimes be deranged and disorganised before evidence suggestive of dementia comes to light during a structured interview. To cite an example, in the course of a cross-sectional examination, a differential diagnosis between dementia and states of subacute clouding of consciousness can be difficult or impossible. Yet given a few items of information regarding the history and development of the condition and the background of the individual, the diagnosis rarely presents difficulties.

Differential diagnosis

Both in respect of therapy and scientific investigation, the failure to differentiate between forms of dementia attributable to different aetiological processes would serve to obscure important findings. Multi-infarct dementia requires to be differentiated from Alzheimer's Disease and the Ischaemia Score (Hachinski *et al*, 1975) has made a start in relation to this. Means of refining the Hachinski score have been suggested (Roth, 1981) and they have been incorporated in the interview described here. Again, clouded and delirious states need to be separated from the dementias. Doubts about diagnosis can be resolved by information relating to the development of the disorder, the previous medical history and evidence regarding drug and alcohol abuse. The record of previous psychiatric illness and family history can help in the differentiation of pseudo-dementia from true dementia. The family record can also assist in the differentiation of Alzheimer's disease of 'early' and 'late' onset; an excessive prevalence of dementia in first degree relatives has been found more commonly in 'early' cases (Heston, 1984).

Measurement of the range and severity of cognitive impairment

A scale for the objective assessment of cognitive function is an essential component of any systematic schedule for the diagnosis and precise delineation of dementia. Subjective complaints of poor memory and word finding difficulty have been shown to be

more influenced by depressed mood than by objective evidence of cognitive impairment (e.g. Kahn *et al*, 1960). The cognitive section of the GMS and the CARE have therefore to be interpreted with caution, since they contain a large number of self-report items. Nor are standard mental status questionnaires, of which there are a large number, adequate for this purpose. Although they employ objective tests, they are usually concerned only with memory and orientation and designed for use with a markedly impaired population. A cognitive function test must sample a broad enough range of functions to meet diagnostic criteria for dementia: DSM-III for example, requires the demonstration of a generalised loss of cognitive functions including language, praxis, perception, abstract thinking and constructional ability as well as memory. Both the older and some of the more recent schedules fail to meet these requirements.

The Mini Mental State Examination (MMSE) of Folstein *et al* (1975) appears to be the best brief objective cognitive test currently in use as part of a diagnostic schedule (it has been incorporated into the DIS), but even the MMSE fails to assess perceptual ability and abstract thinking, and permits only a rudimentary assessment of most other functions. For this reason, we have developed our own cognitive test as part of the diagnostic schedule. However, given the popularity of the MMSE and its use in the influential survey of elderly community residents currently being undertaken by the National Institute of Aging in the USA, we included the Mini Mental State Examination in our cognitive section to enable direct comparisons with the results of other investigators.

A further requirement for a research diagnostic tool, is the reliable grading of severity of dementia. A number of rating scales have been developed in recent years notably the Clinical Dementia Rating (CDR) of Hughes *et al* (1982) and the Global Deterioration Scale (GDS) of Reisberg *et al* (1982). The CDR rates dementia along a five-point scale (none, questionable, mild, moderate, severe) on the basis of the person's performance in six areas of daily living: memory, orientation, judgement and problem solving, community affairs, home and hobbies, and personal care. The criteria are not easy to apply in practice, but questions also arise regarding their validity. Patients may receive the same rating (e.g. CDR 1 or mild dementia) whether or not they have additional difficulty with language or praxis. Yet in a 12-month follow-up study, a poorer prognosis has been reported for patients who had such difficulty at the initial assessment. Patients who progressed to moderate (CDR 2) or severe dementia (CDR 3)

performed significantly worse when originally assessed on all tests of language and praxis as well as on most memory tests (Berg *et al*, 1983). Findings such as these make it imperative that all areas of cognition should be taken into account when arriving at a severity rating. The Global Deterioration Scale (GDS) of Reisberg *et al* (1982) grades cognitive impairment along a seven-point scale, but the criteria rely very heavily on the severity of memory disorder. While we acknowledge that grading the severity of dementia is not an easy task, we propose to show that a clinical assessment of severity based on a range of cognitive tasks and activities of daily living can be made in a reliable way.

In its present form, the CAMDEX focuses on the diagnosis of dementia, with particular reference to its mild forms and to the identification of specific types of dementia. This task requires the differentiation of dementia from non-dementing conditions which may masquerade as dementia. Hence items relevant to other diagnoses must be included. Such items, particularly those relating to depression and paranoid states, are also needed to complete the clinical picture in dementia and are of therapeutic importance. At a later stage when an adequate body of CAMDEX data for patients with a wide range of psychiatric diagnoses has been collected it may be possible to broaden the CAMDEX into a comprehensive diagnostic instrument for psychiatric disorders of the elderly.

Objectives in the development of the present schedule

We have attempted in the development of the schedule which we have called the Cambridge Mental Disorders of the Elderly Examination (CAMDEX), to remedy the gaps in the existing standardised interviews and scales of measurement. We understand that since we began work on this project additional sections are now being added to the GMS to provide this information (Copeland, personal communication).

In developing the CAMDEX we have sought to create a diagnostic schedule with the following main ingredients.

- (1) A structured psychiatric interview with the respondent incorporating questions regarding the present mental disorder and the past history and family history.
- (2) The objective evaluation of a broad range of cognitive functions.
- (3) A standardised schedule for recording observations of the present mental state together with appearance and demeanor.

- (4) A structured interview with a relative or other informant able to provide independent information regarding the respondent's present state, any changes in personality and activities of daily living, past history, and family history.
- (5) A brief physical examination including neurological examination.
- (6) A record of a range of laboratory findings and present medication where applicable.

The CAMDEX schedule

In its present form this schedule comprises a number of sections which are outlined below. It starts with a sheet on which basic demographic data are recorded.

Section A

This section covers items of enquiry regarding the patient's present physical and mental state and in particular seeks symptoms relating to organic psychoses, depression and functional paranoid psychoses. Enquiries regarding past history and family history are also made. The questions posed in the final part of this section are prompted by the preliminary evidence suggesting a relationship in Alzheimer's disease on the one hand, and Down's syndrome and leukaemia on the other (Heston & Mastri, 1977). The section starts with three simple questions; the patient's name, age and date of birth. If the patient fails to provide satisfactory answers to two out of three questions the interviewer abandons Section A and moves on to Section B.

Section B

This consists of the cognitive examination. The 19 items which comprise the widely used Mini Mental State Examination (MMSE) of Folstein *et al* (1975) are incorporated into this section. However, a number of additional items have been included to compensate for weaknesses in the MMSE. First, the MMSE does not sample certain cognitive functions e.g. abstract thinking and perception, which are relevant to diagnosis and are included in DSM-III operational criteria for primary degenerative dementia. Second, many functions are assessed by the MMSE in insufficient detail. For example, memory is assessed only by the repetition and recall of three words; we have added items covering remote and recent memory and the recall and recognition of new information. (For full details of the cognitive examination see Huppert *et al*, 1985.) Thus the

cognitive section of the CAMDEX provides a wider coverage of cognitive functions than the MMSE, as well as more information about most functions. The test assesses orientation, language, memory, praxis, attention, abstract thinking, perception and calculation. Parts of each interview have been recorded so that various aspects of spontaneous speech and the content of language can be systematically assessed later.

Section C

This consists of the interviewer's observations on the patient's appearance, behaviour, mood, speech, mental slowing, activity, insight, thought processes and level of consciousness, and any bizarre behaviour. The section is completed at the end of the interview.

Section D

This comprises a simple physical examination including blood pressure, superficial and tendon reflexes, gait, defects of hearing or sight, tremor and Parkinsonian features to provide some of the information needed for differentiating between 'primary' and 'secondary' dementias.

Section E

The results of laboratory and radiological investigations are recorded in this section. Blood count, B₁₂ and folate, urea and electrolytes, liver function tests, VDRL, skull X-ray and CT scan, are recorded whenever available.

Section F

A record is set down of any medication currently being taken by the patient, and a note of the approximate period during which drugs have been taken.

Section G

This provides for any additional items of information obtained in the course of the interview. The purpose of this section is to amplify the picture of the patient already obtained by the structured questions. Much information in this section is spontaneously offered and of interest on this account alone in addition to the help it may afford to formulate a diagnosis at the end of the interview, particularly in atypical and difficult cases.

Section H

This comprises the structured interview with a relative, or a carer who knows the patient well. Any personality change, difficulty in functioning in everyday life or indications of cognitive difficulty noticed by the carer are noted. Items which permit the Newcastle Dementia Score (Blessed *et al*, 1968) to be scored are incorporated in this section. Questions referable to the presence or absence of depressive or paranoid phenomenology are included. Family history and past history are investigated with the aid of questions similar to those asked of the patient.

At the end of the interview, the interviewer makes a psychiatric diagnosis based on all relevant and available information according to operational diagnostic criteria. Diagnoses are assigned to one of 11 categories: normal, four categories of dementia (senile dementia of the Alzheimer type (SDAT), multi-infarct dementia (MID), mixed SDAT and MID; dementia secondary to other causes), two categories of clouding or delirium (clouded state, clouded state with dementia), depression, anxiety or phobic disorder, paranoid or paraphrenic illness and other psychiatric disorder. Patients are also graded for severity of dementia and severity of depression each on a five-point scale.

Duration of administration

The administration of the respondent's part of the interview can be completed in about 60 minutes. The informant's section takes about 20 minutes.

Test procedure

Subjects

Forty patients (33 female and 7 male) over the age of 65 were interviewed for the reliability study. The main diagnostic categories are given in Table I. A further 52 patients were interviewed (R.G.) so that clinical diagnostic scales could be developed and the cognitive tests used on a larger population. There were 61 females and 31 males in all. They were recruited mainly from inpatients and outpatients from the Department of Geriatric Medicine at Addenbrooke's Hospital, Cambridge, and the Department of Psychogeriatrics, Fulbourn Hospital, Cambridge. The normal group consisted of both geriatric patients and community residents, chiefly from warden-controlled sheltered accommodation.

TABLE I

<i>Interviewer diagnosis</i>	<i>Observer diagnosis</i>			
	<i>Normals</i>	<i>Dementia</i>	<i>Clouding</i>	<i>Depression</i>
Normal	9			
Dementia		22		
Clouding		1	4	
Depression	1		1	2

Method

The 40 patients participating in the study of inter-rater reliability were rated at the same time by two psychiatrists; one acting as interviewer for the whole interview and the other as observer. Both psychiatrists completed the CAMDEX independently. One psychiatrist (E.T.) was present at the interview of all patients and was the interviewer in half the interviews. Three other psychiatrists (H. H., S. V., R. G.) took part in the reliability study. Two of the four psychiatrists were trained in the UK and two in the USA. For each patient the ratings of the two psychiatrists were compared for all items and for each section of the CAMDEX. The purpose of the item analysis was to identify the questions with a high rate of disagreement between interviewers so that the source of the disagreement could be ascertained and the question modified or discarded from the next edition of the schedule.

The agreement between interviewers was measured by means of the phi (ϕ) coefficient (Guilford & Fructer, 1981). Although ϕ can vary from -1 to $+1$, only under certain conditions can the coefficient be as extreme as either of these limits. It is only when the two means are identical that the coefficient equals 1. The degree of difference between means is reflected in the degree of reduction in the value of the ϕ coefficient.

Results

Inter-rater reliability

Diagnostic agreement

There was good agreement between pairs of psychiatrists in the main diagnostic groupings (Table I). There was complete agreement on cases diagnosed by the interviewer as normal or demented. One of the five cases diagnosed by the interviewer as clouded was classed as demented by the observer, while of the four cases diagnosed by the interviewer as depressed, the observer agreed on two, but classed one as normal and one as demented.

The ϕ coefficient for diagnostic agreement was reduced to 0.63 when dementia was subdivided into four diagnostic categories: SDAT, MID, mixed SDAT and MID and dementia secondary to other causes. There was complete agreement between raters on the ten cases diagnosed by the interviewer as SDAT and one case of secondary dementia. Two of the eight cases diagnosed as MID were classed as

TABLE II
Inter-rater reliability of sections of CAMDEX

Section	ϕ Coefficients (2 × 2 agreement/ disagreement on individual items)		Pearson correlations of total scores for each section	
	Median	Range	r	P
A Interview with patient	0.94	1.0–0.28	0.99	0.000
B Cognitive examination	0.90	1.0–0.30	0.97	0.000
C Observations	0.83	1.0–0.30	0.81	0.000
H Interview with informant	0.91	1.0–0.56	0.90	0.000

mixed by the observer, and one of the three cases diagnosed as mixed was classed as SDAT by the observer.

Agreement on subsections of the scales

The ϕ coefficient was calculated for each item in Sections A, B, C and H of the CAMDEX. Table II presents the median and range of these values.

It will be seen that all the median coefficients for sections are high. The lowest value obtained was derived from the record of observed behaviour (Section C) independently set down by the two psychiatrists, but at 0.83 this section may be judged satisfactory and to show an acceptable degree of inter-observer agreement.

Some idea of the reliability of the items can be obtained from the range of ϕ coefficients estimated for the different items in each section. The item with the lowest reliability in Section A was the judgement by the psychiatrists as to whether physical disability accounted for the patients' inability to deal with household tasks (ϕ 0.28). The item with lowest reliability in the cognitive examination (Section B) concerned the naming of as many different animals as possible in a minute (ϕ 0.30). This wide disagreement was traced to the fact that one of the raters had excluded fish or birds. The poorest item in the observation section (Section C) was "Speech very slow. Pauses between the words" (ϕ 0.33). In such cases, scoring instructions have been made more explicit to increase reliability in the revised version.

The answers recorded from relations or carers (Section H) showed very good agreement between raters. The item with the lowest ϕ coefficient was "Does he/she have difficulty in knowing where he/she is or in recognizing you?" (ϕ 0.53). This is probably too terse and ambiguous for lay persons and has been made more specific in revision.

However, the proportion of items with low ϕ coefficients proved relatively small. The great majority of items reached an acceptably high inter-rater reliability.

Correlations between the total scores obtained by the two psychiatrists for each section are also shown in Table II. The correlations are all high and very significant statistically.

Cognitive performance

The results presented here were for the whole sample of 92 patients. The diagnoses in the total group were 17

normals, 26 with SDAT, 13 with MID, seven mixed SDAT and MID, three with dementia secondary to other conditions, five clouded-delirious (hereafter called clouded state), nine clouded states superimposed on dementia, and 12 depressed patients. For the three cases where interviewer and observer disagreed about the diagnosis, the interviewer's diagnosis was used. There was no significant difference between diagnostic groups in respect of sex or age of the patients, except that the depressed patients were significantly younger (71.9) than the normal (79.5), SDAT (79.3) and MID (80.1) groups.

Sensitivity and specificity

From the cognitive section (Section B) we obtain two overall measures of cognitive function: (a) total score on the Mini Mental State Examination (MMSE) of Folstein *et al* (1975) and (b) total score on The Cambridge Cognitive Examination (CAMCOG) which consists of 14 of the 19 MMSE items plus 43 items covering additional aspects of cognitive function. Maximum scores are 30 on the MMSE and 106 on the CAMCOG.

Table III shows the cognitive scores in the four major diagnostic groups. The normal and depressed groups did not differ significantly from each other on either test but performed markedly better than either the demented or clouded groups ($P < 0.001$) which did not differ from each other.

The sensitivity and specificity of the two tests for detecting organic mental impairment have been calculated. For the MMSE a cut-off value of 21/22 was recommended for those aged 60 or over (Anthony *et al*, 1982). Using this cut-off we obtain values of 96% sensitivity and 80% specificity for our population. This means that 96% of cases with an MMSE score of 21 or less had a clinical diagnosis of organic mental disorder (dementia or clouded state) while 80% of cases with an MMSE score of 22+ had been diagnosed as normal or depressed. Conversely, 20% of those scoring 22+ had a clinical diagnosis of organic mental disorder and hence were misclassified using this cut-off. We found that the optimal cut-off for our sample, was 23/24 which yielded 94% sensitivity and 85% specificity.

Sensitivity and specificity of the CAMCOG were also calculated. Examination of the distribution of scores showed the optimal cut-off to be 79/80. This yields 92% sensitivity and 96% specificity. Only one organically

TABLE III
Total scores for the Cambridge Cognitive Examination (CAMCOG) and the Mini-Mental State Examination (MMSE) in the major diagnostic groups

	Mean and range of CAMCOG scores (maximum = 106)		Mean and range of MMSE scores (maximum = 30)	
Normal (n = 17)	90.0	(72–101)	26.7	(22–29)
Demented (n = 49)	44.2	(8–82)	13.4	(1–25)
Clouded (n = 14)	52.3	(38–79)	15.3	(9–27)
Depressed (n = 12)	83.9	(68–98)	24.8	(14–30)

impaired patient was misclassified by this instrument compared with four who were misclassified by the MMSE.

Several patients obtained maximum or near maximum scores on the MMSE. Sixteen patients scored 27+, including five depressed and one clouded patient. Five patients scored 29+ (three normals, two depressed), the highest score (30) being obtained by a depressed patient. In contrast, only two patients, both normals obtained a CAMCOG score of 100+ while an additional two (one normal, one depressed) scored within 10 points of the maximum, and a further five (two normal, three depressed) scored within 20 points of the maximum. These findings demonstrate that CAMCOG can discriminate between individuals even at the high end of the ability range.

Severity of dementia and cognitive function

The relationship between cognitive performance and severity of dementia was examined by correlating both the dementia score (Blessed *et al*, 1968) and the clinical rating of severity of dementia with scores on the cognitive tests. For the group as a whole, all correlations were highly significant ($P < 0.000$). The dementia score correlated -0.70 with the CAMCOG and -0.66 with the MMSE. The clinical rating of severity of dementia correlated -0.78 with the CAMCOG and -0.76 with the MMSE. There was a correlation of 0.94 between the two cognitive tests and 0.68 between the dementia score and the clinical rating of severity.

The dementia score correlated significantly with each of the eight subscales of the Cambridge Cognitive Examination (orientation, language, memory, praxis, attention, abstract thinking, perception and calculation). The clinical rating of severity of dementia also correlated highly with the cognitive subscales ($P < 0.000$ for all comparisons).

Within the demented group as a whole ($n = 49$) there was very good agreement between cognitive performance and the clinician's estimate of severity of dementia. The correlation was -0.83 for the total score on the CAMCOG and -0.69 for the score on the MMSE. The correlation was highly significant for each of the eight cognitive subscales, the highest correlation being obtained for language (-0.77) and the lowest for attention (-0.40 , $P = 0.004$).

Subjective assessment of cognitive function

Cognitive function was reported subjectively by the patient in Section A of the CAMDEX and reported by the informant in Section H. We examined the relationship between this type of information and objective measures of cognitive performance. Three questions in Section A were concerned with the patient's self-assessment of memory; a general question about memory difficulty, a question about misplacing objects and a question about losing one's way in familiar surroundings. None of these correlated significantly for the group as a whole, with performance on the memory items or any other measures of cognitive performance. Questions about difficulty with concentration, slowing of speech or slowing of thoughts also failed to correlate significantly with cognitive performance. On the other hand, the responses of

informants to five questions about memory, concentration and muddled thinking, all correlated highly ($P < 0.001$) with total score on the CAMCOG and ($P < 0.01$) with seven of the eight cognitive subscales (orientation, language, memory, praxis, attention, abstract thinking, perception) while all failed to correlate with the calculation subscale and a measure of reading ability.

A question about word-finding difficulty was also asked of both the patient and the informant. Patient's self report did not correlate significantly with objective measures of naming or verbal fluency although it correlated significantly with measures of verbal memory ($P < 0.01$). The informant's evaluation of the patient's word-finding difficulty correlated significantly ($P < 0.01$) with both naming and fluency, and with each of the main cognitive subscales except memory.

In general it may be concluded that the patient's self report of cognitive function bears no relation to cognitive performance whereas the informant's judgment provides a reliable guide. Consistent with this is the absence of any significant correlations between patients' and informants' reports of the patient's of cognitive function.

Depressed mood and cognitive function

In addition to making a clinical diagnosis of depression and rating its severity, CAMDEX permits depressed mood to be assessed in all patients. This is done by; (a) self report on 20 items from Section A relating to the signs and symptoms of depression which were added together to provide a depression severity scale, and (b) the informant's response to the question, "Do you think he/she is depressed?". We examined the relationship between these measures and cognitive performance.

For the group as a whole, scores on the depression severity scale are significantly related to orientation and memory performance ($P < 0.01$) but not to any other measure of cognitive performance. The informant's assessment of depressed mood correlated significantly ($r = 0.30$, $P < 0.01$) with scores on the depression severity scale but not with any measure of cognitive function.

Responses to a key item in the depression severity scale ("Do you feel sad, depressed or miserable?") were found not to be related to cognitive performance, but correlated 0.64 ($P < 0.001$) with informant's assessment of depression. These findings indicate that the presence of the signs and symptoms of depression is related to impaired memory functioning but complaints about depressed mood are not.

Development of the clinical diagnostic scales

The number of patients in the SDAT, MID and depressed groups was sufficiently large to consider the development of a diagnostic scales from items in the CAMDEX. The first stage was to select items considered, on clinical grounds, to be of possible use in making differential diagnoses. The frequency distribution of these items was drawn up for all diagnostic groups recorded on the CAMDEX and those items which proved to differ in frequency between diagnostic groups were selected for the development of three diagnostic scales. The first intended

FIG. 1. Mean scores on diagnostic scales for four diagnostic groups. (Scores adjusted for scale score mean)

as a scale for SDAT consisted of 18 items and proved to be a scale of organicity in general. The second was a scale for MID which consisted of 12 items, and the third for depression consisting of 14 items. The scores on these subscales plotted by the diagnosis made on the basis of operational diagnostic criteria is illustrated in Fig. 1.

The cumulative frequency curves of the scores in each scale were plotted for SDAT, MID, depressed and normal groups, (Figs 2, 3, 4). These graphs were used to determine optimal cut-off points for diagnosis. The proportion of correctly classified patients using these optimal cut-off points is shown in Table IV.

DISTRIBUTION OF ORGANICITY SCORES - 4 DIAGNOSTIC GROUPS

FIG. 2. Distribution of scores on organicity diagnostic scale for normal, depressed, SDAT and MID groups.

FIG. 3. Distribution of scores on MID diagnostic scale for normal, depressed, SDAT and MID groups.

The statistical significance of the diagnostic differentiation between the groups at these cut-off points was tested, using χ^2 tests and Fisher's exact test. Using a cut-off point of 4, the organicity scale differentiated between SDAT patients and normals ($P < 0.0001$) and depressed patients ($P < 0.0005$) but did not differentiate

between SDAT and MID. A cut-off point of 2 on the MID scale produced significant differences between MID cases and normals ($P < 0.01$), SDAT ($P < 0.0001$) and depression ($P < 0.001$). A cut-off point of 10 on the depression diagnostic scales produced significant differences between depressed patients and normals ($P < 0.0001$), SDAT

FIG. 4. Distribution of scores on depression diagnostic scale for normal, depressed, SDAT and MID groups.

TABLE IV
Classification of diagnoses by clinical diagnostic scales using approximate cut-off points

	Cut-off score	% Correctly classified			
		Normal	SDAT	MID	Depression
Organicity scale	4	100	85	85	92
MID scale	2	95	85	85	83
Depression scale	10	100	100	85	75

($P < 0.0001$) and MID ($P < 0.01$). It has to be borne in mind of course that there can be no complete differentiation since the conditions are not mutually exclusive in reality as is probably reflected in cases of depression and MID.

The independence of the three scales was tested by calculating their inter-correlations. These showed that there was a high degree of independence between the depression scale and the other two scales ($r = -0.15$ and 0.18 for organicity and MID scales respectively) although a significant relationship between the organicity and MID scales was found.

A test of reliability of the scales was made by an odd-even-split-half method. The reliability coefficients were corrected to full length and are shown below. A particularly high level of reliability is shown for the organicity scale (0.95). The other two scales for depression (0.90) and MID (0.77) seem quite acceptably reliable.

The problem of validity is difficult. A clinical diagnosis made under these circumstances cannot be fully independent of responses to items in the scale since the items are based on similar considerations to those on which clinical judgement is based. This is, of course, substantially why the items are included in the scale at the outset. Equally the expectations resulting from a clinical diagnosis probably create some bias in the evaluation of responses to the scale items, where the scale is administered by the diagnostician. Difficulties of this kind are incapable of complete resolution and validation becomes a progressive process of iterations, in which many varied sources of information must be used. In the present research the scales described are derived only from clinical data and, therefore, it is possible to turn to the cognitive section to look for validation. A positive correlation would show a relationship between a scale and some aspect of cognitive performance such as to indicate

TABLE V
Correlations between clinical diagnostic scales and factors derived from cognitive items

	Factor 1 (66.5%)	Factor 2 (9.5%)	Factor 3 (6.7%)	Total score on CAMCOG
Organicity	-0.61***	0.19	0.13	-0.63***
MID	-0.27**	-0.10	-0.01	-0.25*
Depression	0.21*	-0.12	0.02	0.22*

(Figures in brackets are variance explained by each factor)

* $P < 0.05$

** $P < 0.01$

*** $P < 0.001$

the scale was a rational measure. It is, of course, to be noted that the absence of a correlation simply would leave the validity question open since the test does not propose a relationship of any hypothetical kind.

Items from the cognitive section were subjected to a principal component analysis and the resulting factor scores of the first three factors were also correlated with the three scale scores. The pattern of results for Factor 1, a general factor, was strikingly similar to that obtained for the total score on CAMCOG as a whole (Table V). Both correlated highly with the organicity scale giving substantial support for its validity. There is also a smaller but statistically significant correlation with the MID and depression diagnostic scales.

The organicity and MID scales also correlated significantly with the psychiatric global rating of dementia though not with global ratings of depression. The reverse was true of the depression diagnostic scale which correlated highly with the clinical global rating of depression (Table VI).

TABLE VI
Correlation coefficients between clinical diagnostic scales and global ratings of severity

Clinical scale	Dementia	Depression
Organicity	0.73***	-0.11
MID	0.28**	0.15
Depression	-0.25	0.74***

** $P < 0.01$

*** $P < 0.0001$

Eight of the 18 items in the organicity diagnostic scale are items which also appear in the Newcastle Dementia Scale for severity of dementia (Blessed *et al*, 1968) and there is therefore a high correlation between the two scales (0.95) although the Blessed scale did not differentiate satisfactorily between diagnostic groups.

Discussion

In this paper we have described a diagnostic and assessment schedule that seeks to evaluate all parameters of present state, history, observation and measurement that may be relevant for the purpose of diagnosis and quantitative gradation of dementia.

Each section of the CAMDEX has been found to have an acceptably high measure of inter-observer reliability and this holds also for the great majority of individual items. The measure of agreement between different psychiatrists in respect of broad categories of diagnosis has also proved satisfactory and compares favourably with figures for inter-observer agreement in published schedules directed at the problem of diagnosis alone (Henderson *et al*, 1983). Data relating to test and re-test reliability are for the present limited; there are special problems attaching to the administration within a short period

of a long assessment schedule to elderly individuals. However, agreement between test and re-test within 3 weeks in a small number of cases is good.

The CAMCOG score in the cognitive section proved to have a high sensitivity and specificity in differentiation between organic and non-organic cases and was highly correlated with the Blessed Dementia Scale and the psychiatrist's clinical rating of severity.

Two principal advantages which the CAMCOG has over the widely used Mini Mental State Examination (Folstein *et al*, 1975) are (i) it covers a broader range of cognitive functions (ii) it detects mild degrees of cognitive impairment and (iii) it avoids ceiling effects.

Comparisons between information obtained from patients and their relatives indicates that relatives may be unaware of depressed mood but are far better at assessing cognitive impairment than are patients themselves.

The diagnostic scales derived from the sample show a relatively good classification rate; are reliable as shown by the split half reliability and have some evidence of validity, inferred from their correlations with global clinical ratings and with cognitive performance. These scales must now be tested on a new population so that their utility can be assessed. In the longer term it is planned to use these as the basis for computerised diagnosis, along the lines of the CATEGO classification (Wing *et al*, 1974) and the AGE CAT classification newly developed by Copeland and his colleagues for the GMS, in which organic psychosis is treated as a single category.

It is intended to investigate the validity of the CAMDEX schedule in a number of different ways, including long-term follow-up studies and correlation with pathological and biochemical measures. Examination of cognitive change in the follow-up studies will be of particular importance for the derivation of valid criteria in the diagnosis of early and mild dementia and depressive pseudo-dementia. Post mortem studies of the brain should also prove valuable to this end in addition to shedding light on the structural and neurochemical changes associated with the early stages in the development of dementia which are for the present largely unknown.

For the present the CAMDEX has proved itself of value as an instrumental aid in clinical diagnosis. When determined with the aid of CAMDEX, diagnoses have shown an acceptably high measure of inter-observer correlation. To develop the CAMDEX to the next stage will require additional data derived from the independent methods of validation which have been suggested in this section of the paper.

Assessing and Treating Attention Deficit Disorder in Adolescents

The Clinical Application of a Single-Case Research Design

S. P. KUTCHER

Psychiatric assessment strategies that integrate research findings with daily practice are necessary and clinically useful. This paper uses the example of an attention deficit disorder adolescent to illustrate how double-blind placebo controlled and multi-dose adjustment designs can be successfully implemented in routine clinical practice. These designs are especially valuable in evaluating the therapeutic effect of methylphenidate because of biases that may lead to clinical misuse of this stimulant medication.

It has recently been appreciated that children with attention deficit disorder $\pm$ hyperactivity (ADD) do not outgrow their difficulties at puberty but may continue to experience psychiatric symptoms in adulthood (Menkes *et al*, 1967; Borland & Heckman, 1976; Wood *et al*, 1976; Weiss & Hechtman, 1979; Weiss *et al*, 1979; American Psychiatric Assoc., 1980; Weiss, 1983; Gauthier, 1984). These difficulties often lead to medical referral from parents, schools or correctional institutions and many attention deficit disorder adolescents may be seen by general psychiatrists. Although ADD is relatively common (Bloomingdale, 1984; Taylor, 1985), standard psychiatric textbooks (Hill *et al*, 1979; Kendell & Zealley, 1983) including one specifically concerned with adolescence (Evans, 1983) devote little space to the adolescent aspects of this disorder and low general awareness of adolescent ADD may lead to its underappreciation in this age group.

Significant numbers of childhood hyperactives have adolescent years characterised by continued motor restlessness, deficient problem solving skills, impulsive cognitive styles, delinquency, drug abuse, poor peer relationships, school failure and personality styles of immaturity, recklessness and impulsivity (Weiss *et al*, 1971; Minde *et al*, 1972; Cohen *et al*, 1972; Huessey *et al*, 1972; Stewart & Mendelson, 1973; Mendelson *et al*, 1974; Satterfield, 1981; Hechtman, 1984). Intrapsychically they tend to have low self esteem (Stewart & Mendelson, 1973; Mendelson *et al*, 1974; Weiss, 1983) and those adolescents with learning disabilities or conduct disorders have poorer outcome when concurrently

suffering from ADD (Ackerman *et al* 1977; Offord *et al*, 1979). Symptomatic ADD may prevent appropriate completion of adolescent maturational tasks (Erickson, 1950; 1968) leading to adult vocational, interpersonal and intrapsychic difficulties (Bellak, 1979) and successful clinical intervention during the adolescent years may have long-term benefits (Gittleman, 1983; Weiss, 1983; Cantwell, 1984).

Although long-term studies have yet to be reported, recent pharmacologic research has identified positive short-term effects of stimulants in the treatment of adolescents with ADD, and has not shown evidence of previously postulated excitatory switch effects at puberty (McKay *et al*, 1973; Safer & Allen, 1975; Lerer & Lerer, 1977; Barkley, 1977; White, 1981; Varley, 1983).

These results suggest a potentially helpful intervention strategy in the treatment of the ADD adolescent for whom the various psychotherapies have not been shown to be effective.

Pharmacological treatment studies, however, carried out in groups of patients with outcome data presented as population means offer few helpful guidelines for routine clinical practice. Individual physiologic, intrapsychic, social and interpersonal factors may all affect drug response and clinician bias towards stimulant therapy may influence decisions about instituting or evaluating treatment (Taylor, 1985). The use of the single-case research design (Kazdin, 1983) offers a potentially valuable tool in routine clinical assessment and treatment of ADD adolescents. It provides an objective measure of

stimulant effectiveness in the individual case, discouraging both overenthusiastic prescription or *a priori* rejection of drug therapy.

This paper uses the example of an adolescent assessed with this design to provide a practical guideline that could be readily applied in the routine clinical assessment of ADD adolescents, by adolescent specialists and general psychiatrists alike.

The Patient

D. S. a 14-year-old boy living at home with his mother and two younger brothers was admitted to a psychodynamic milieu orientated treatment centre. He had a history of thieving from cars, running with a gang, poor academic performance, anti-authority behaviour and poor peer relationships. School difficulties led to his placement in a 'Summerhill'-type residential school which had then for 2 years encouraged his free expression before finding his behaviour intolerable. The educational psychologist who referred him following his expulsion from that school described him as "a severely emotionally disturbed child locked in a constant battle with his mother". His mother stressed D. S.'s impulsiveness, anti-authority stance and his inability to learn from his mistakes.

D. S. was born of an unplanned pregnancy when his mother was 16 years of age. There were no natally associated difficulties and developmental milestones were reportedly normal. As a child, he was described as 'hard to discipline', 'full of excess energy', 'on the go', 'impulsive', 'accident-prone', and 'unable to wait his turn at games'. He had major school difficulties with reading and mathematics, paying attention in class and had failed grades.

His family life had been characterized by violent disagreements between his parents which culminated in their divorce when he was 8 years of age. His maternal grandfather had a history of excessive gambling and a maternal uncle was described as having low self-confidence and difficulties relating to people. His paternal grandfather was an alcoholic and his biological father had been jailed for assault and was prone to impulsive, angry, violent outbursts.

Method

Mental state

On examination, D. S. presented as a 'cocky lad' with a sense of bravado. He was easily engaged but was restless and fidgety. He spoke reasonably about what he thought his difficulties were: acting without thinking, fighting, not getting on with others, an overly quick temper, trouble

sitting still, trouble concentrating and feeling badly about himself (low self-esteem). He was not depressed nor thought-disordered. He thought little of the future and had no vocational plans, feeling that schooling was a "waste of time".

Physical

Physical examination showed a healthy adolescent; however, he had difficulties with rapid alternating movements, fine motor movements and balance. Drawing tests showed visuospatial difficulties. An EEG showed no seizure focus but excessive artifact secondary to his motor restlessness. Routine serology was within normal limits.

Educational

Educational assessment carried out by the Unit's teacher gave a reading age of 10.4 and a comprehension age of 11.4 on the Neale Reading Test. A Burt Spelling Test gave an age score of 10.0. Mathematics Operations were at the 9 year level and he was unable to apply basic arithmetic skills to problem solving.

Psychological

A Wechsler Intelligence Scale for Children (WISC) showed a performance IQ of 83 and a verbal of 86, although the testing psychologist felt these were underestimations secondary to 2 years of minimal academics. The coloured version of the Standard Progressive Matrices gave a score at the 11.5 year level and the Embedded Figures Test showed 20% correct responses to the house figure. A Rorschach was interpreted as within normal limits.

Pharmacological

Following a 2-day baseline assessment period a double-blind placebo cross-over trial (ABAB design) implemented, with the co-operation of the hospital pharmacologist, of methylphenidate 10 mg orally (0.16 mg/kg) three times daily was begun. The trial was maintained throughout periods of weekend leave at home.

D. S. was rated on an 18-item five-point scale (Appendix 1) derived from the Conners Scale (Conners, 1969) to which were added items related to the diagnostic criteria of Attention Deficit Disorder + Hyperactivity of DMS-III (1980). Ratings were independently made by nursing staff, physicians and teacher, and the scores for each day, were totalled and averaged for nurses, doctors and teachers separately, to determine the daily score by discipline.

Because this trial demonstrated a positive effect, a blind multi-dose trial of methylphenidate at 10 (0.6 mg/kg), 15 (0.9 mg/kg) or 20 (1.2 mg/kg) mg orally three times was then instituted. During this trial, both D. S. and his mother participated in the ratings. For each dose block (4 days per block) the daily scores were totalled and averaged to determine the block total score.

FIG. 1 ABAB, single case design, methylphenidate trial treatment response ($P < 0.01$).

FIG. 2. Methylphenidate blind multi-dose trial: treatment response.

Results

For the double-blind placebo cross-over design (see Fig. 1), the baseline score gave a mean value of 50.0 ± 3.2 . The scores for the two medication periods were 24.1 ± 2.3 and 22.6 ± 2.4 . Each medication period was associated with a

greater than 50% symptom reduction in comparison with the two placebo periods and baseline assessment ($P < 0.02$, student's *t*-test).

The baseline score for the blind multi-dose trial gave a mean of 71.2 ± 22.6 (Fig. 2). The scores for the medication blocks were: block A (0.9 mg/kg) 30.2 ± 8.7 ; block B (1.2 mg/kg) 30.0 ± 7.7 and block C (0.6 mg/kg) 31.5 ± 8.4 . Although symptom scores of all three medication blocks differed by more than 50% from the non-treatment baseline, there were no significant differences amongst blocks ($P > 0.5$, student's *t*-test) (Fig. 2). Nursing and teacher observations regarding side-effects and D. S.'s self report noted the presence of drowsiness and lethargy during the block B (1.2 mg/kg) medication period.

Therapeutic intervention was tailored to D. S.'s needs as identified by the assessment studies, on a multimodal basis. Methylphenidate was begun at a dose of 10 mg orally three times daily (0.6 mg/kg). Individual remedial education, social skills training and insight oriented group therapy were implemented. Attempts were made to involve D. S. in pottery and woodworking, two areas in which he showed aptitude, to help improve self-image. Family therapy was continued.

The institution of methylphenidate treatment was associated with noted changes in D. S.'s behaviour. Staff found him to be less disruptive and more amenable to direction, decreasing conflict with authority figures. His group skills improved and fighting diminished. His mother reported a positive change in weekend home visits and individual meetings with him about his medications helped develop insight into his difficulties and hope about the future.

Discussion

This single-case study design illustrates many of the fundamental issues of clinical assessment in an impulsive, inattentive and overactive adolescent who presented with intrapersonal, social, educational and family difficulties. First, an appropriate diagnosis of attention deficit disorder with hyperactivity was made—because of an awareness of this presentation in the adolescent age group. It would have been possible to explain D. S.'s problems solely in terms of sociopathy or psychodynamic conflicts which may have precluded pharmacologic, behavioural or social interventions.

In this case the diagnosis of attention deficit disorder with hyperactivity was made using DSM-III criteria (1980). These criteria highlight the inability to sustain attention as the central feature of the syndrome, thus shifting the emphasis from overactivity as described in both DSM-II and ICD-9 in which the terms 'hyperkinetic reaction' and 'hyperkinetic syndrome of childhood' are used. This change in focus, although not universally acknowledged may have greater diagnostic utility than behavioural overactivity (Cantwell, 1984) and may

improve a clinician's ability to differentiate this syndrome from age-appropriate overreactivity or overactivity secondary to a chaotic environment.

Further, the diagnostic criteria as found in the DSM-III (1980) are more clearly defined than previously, thus potentially providing greater consistency in clinical diagnosis. Also, by permitting more than one diagnosis to be entered on Axis I, DSM-III (1980) supports concurrence of this syndrome with conduct disorder (in this case conduct disorder, socialized, non-aggressive). Previous comparisons of diagnostic practices between the United Kingdom and North America have reported similarly high rates of hyperkinetic behaviours but up to a 20-fold difference in the syndromal diagnosis of hyperkinesis (Taylor, 1985). The effect of the DSM-III diagnostic system, particularly its focus on attention deficit and the coding of multiple non-hierarchical diagnosis on future epidemiological comparisons remains to be fully studied.

It should be noted that a positive response to methylphenidate both in terms of diminished activity or an increase in attention maintenance does not of itself confirm a diagnosis of ADD. Stimulants may improve symptoms of restlessness and scores on attention-related tests in both overactive and non-hyperactive children with conduct disorder (Taylor, 1983), and have been reported to decrease motor activity and improve vigilance in both hyperactives and normal controls but more so in the hyperactives (Rapoport *et al*, 1980). Sustained attention as measured by reaction time tasks however, improved selectivity in the hyperactives only. Thus although methylphenidate treatment may improve the symptoms of ADD, symptomatic improvement is not diagnostically specific.

The drug trial design illustrated in this case provided objective evaluation of two related treatment issues. First, use of a double-blind cross-over methylphenidate trial during the assessment period provided objective data about the potential value of pharmacological intervention, showing a significant treatment response to methylphenidate. Secondly, the blind multi-dose treatment trial allowed clinical titration of drug effect that balanced behavioural control against overmedication and side-effects.

This second trial showed slightly higher scores both at baseline and at treatment perhaps reflecting the influence of environmental factors, as some major changes including changeover of treating physician had occurred in the Unit between the two trials. However, the initial treatment response was replicated. There was no significant difference in

symptom reduction amongst methylphenidate doses of 0.6 mg/kg, 0.9 mg/kg and 1.2 mg/kg thus identifying a minimum dosage for effective behavioural control without missing potential higher dose responders and reducing the possibility of dose-related methylphenidate side-effects previously described by Sprague and Sleator (1977), and Greenhill *et al* (1984).

These designs proved easy to incorporate into ward routine. Total staff time required was estimated at less than 2 hours and treatment effect of methylphenidate was apparent within 2 weeks of beginning the trial. Inpatient stays of 3-6 months are not uncommon in adolescent treatment units and the objective rapid evaluation of methylphenidate effect as determined by these assessment designs may potentially decrease admission length, providing more cost-effective service without sacrificing comprehensiveness of care.

The use of these assessment studies had beneficial effects for the treatment unit as well. Initial staff scepticism about the use of drugs in adolescents was modified by the objective data derived from the trials leading to an increased vigour in D. S.'s therapy. The assessment model provided a 'live' experiment illustrating that pharmacologic and psychodynamic approaches can successfully complement each other in the treatment of the disturbed adolescent.

Double-blind cross-over and multi-dose treatment trials of methylphenidate should be an integral part of the clinical assessment of the ADD adolescent. Their routine use allows the clinician to bridge the gap between research studies reported in the literature and the multiple presenting problems of the individual adolescent. They provide objective measures of pharmacologic effect and also have psychologic treatment utility. These designs are cost-effective and provide immediate objective verification of clinical response relatively free from placebo effect and negative or overly optimistic attitudes of adolescents, parents and treatment staff towards stimulant medications.

With the involvement of a responsible parent this design can be modified for outpatient assessment. In the adolescent undergoing long-term methylphenidate treatment future changes in stimulant dosage can be similarly assessed, and behavioural responses compared to initial presentation thus increasing the effectiveness of long-term treatment monitoring. Regular clinical use of these assessment strategies may lead to more appropriate pharmacotherapeutic interventions in adolescent ADD and should prevent stimulant drug misuse.

Computed Tomographic Density Numbers A Comparative Study of Patients with Senile Dementia and Normal Elderly Controls

J. COLGAN, M. NAGUIB AND R. LEVY

Cranial computed tomography (CT) scans of 48 patients with senile dementia of the Alzheimer type (SDAT) and 40 normal elderly volunteers were compared. The demented group were found to have significantly larger lateral ventricles assessed planimetrically and by using a linear measure of the ratio of the maximum width of the frontal horns of the lateral ventricles to the maximum intracranial diameter. Attenuation density was computed for 15 brain regions. The demented group did not differ significantly from the normal controls with respect to attenuation density in any of the regions studied.

Reports on computed cranial tomography (CT) generally concur in the finding that patients with senile dementia have larger lateral and third ventricles than normal elderly controls (Jacoby & Levy, 1980; Gado *et al*, 1982). Similarly patients with senile dementia have been shown to have more severe sulcal widening as rated by an experienced neuroradiologist, than normal elderly controls (de Leon *et al*, 1980; Jacoby & Levy, 1980). There is, however, substantial overlap between groups both with respect to estimates of ventricular size and cortical atrophy and were one to make a diagnosis of senile dementia solely on the CT finding then at least 17% of subjects would be misclassified (Jacoby & Levy, 1980).

It is less clear whether patients with senile dementia differ from normal elderly controls with respect to CT attenuation density (Brinkman *et al*, 1981). Some workers including our own group, have reported patients with senile dementia as having lower brain attenuation density than controls (Bondareff & Levy, 1981; Naeser *et al*, 1982), others reported no difference (Wilson *et al*, 1982; Gado *et al*, 1983) and one group found density to increase with the severity of dementia (George *et al*, 1981). Comparison between studies is difficult for several reasons. Different scanners have been used which may not produce comparable density measurements and in one study results obtained using several scanners were amalgamated (Wilson *et al*, 1982). Studies have used differing criteria for subject selection and attenuation density has been computed for regions that are not comparable in site or size.

In view of the conflicting findings concerning CT brain attenuation density in senile dementia, and the paucity of replicative studies using comparable methods, it was decided to use the same CT scanner and method as in the study of Bondareff *et al* (1981) to examine a new, larger, series of elderly demented patients and controls. This method was chosen as it had fewer drawbacks, than others. The use of a very large brain sample area increases the probability of the inclusion of unwanted areas such as sulci and it might be argued that the finding of lower attenuation density in demented patients by Naeser *et al* (1982) reflected the inclusion of atrophic sulci in the whole and quarter slices which they sampled. Conversely the use of very small brain sample areas might be expected sometimes to result in unrepresentative areas of a particular region being sampled. Furthermore, a small shift in the cursor could result in a quite different reading. The use of high convexity and centrum semi-ovale slices, as in the study by George *et al* (1981), introduces the possibility of obtaining elevated density readings in patients with dementia, where with ventricular enlargement these slices selected would tend to be pushed higher. It is recognised that as one approaches the apex, brain density readings increase (De Chiro *et al*, 1978). Similarly brain density readings taken at the convexity of the brain as in the study by Gado *et al* (1983), might be expected to be raised through the inclusion of partially volumed bone although this would affect both controls and patients with dementia. The method chosen for the present study

utilises a brain sample size of intermediate area and avoids high slices and convexity readings.

Method

Subjects

Subjects consisted of a group of 48 patients who were diagnosed as having senile dementia of the Alzheimer type (SDAT) and were hospital inpatients, outpatients, day-patients or attending a day centre. Controls were a group of 40 normal elderly volunteers who were living independently in the community and showed no evidence of dementia or psychiatric disorder. Informed consent was obtained from all participants or, where not possible, the closest relative. The diagnosis of dementia was made on the basis of progressive global deterioration of higher cerebral function, of at least 6 months duration excluding those patients who had histories of stroke, head injury, alcoholism or major psychiatric illness. Other exclusion criteria were the presence of focal neurological signs, a measured blood pressure greater than 160 mmHg systolic or 100 mmHg diastolic and evidence of an underlying cause of dementia such as vitamin B12 or folate deficiency, endocrine disorder, metabolic disturbance or syphilis. All subjects were interviewed using a semi-structured interview [the Geriatric Mental State Schedule (GMSS) (Copeland *et al.*, 1976)], underwent a full neurological examination, were given a test of memory and orientation, The Mental Test Score (MTS) (Hodkinson, 1973) and performed the Digit Copying Test (DCT) (Kendrick, 1965).

Computed tomography

Subjects were examined using the Maudsley Hospital EMI CT 1010 head scanner. Eight slices were made parallel to the orbitomeatal line. An EMI Independent viewing centre (IVC 464) was used to read the scans. Those scans with no more than minimal movement artefact were selected, displayed on a television screen and, by means of a tracker ball, an approximately circular area of 37 pixels was superimposed on anatomical regions of interest in appropriate slices. The mean attenuation density in Hounsfield units (HUs) was then calculated using a computer programme. Further details of the method are described by Bondareff *et al.* (1981). In addition the ventricular-brain ratio (VBR), that is the ratio of maximum ventricular area to internal skull area was determined using a planimeter. The correlation between the VBR of the same scans by independent raters is high ($r=0.98$, $P<0.001$; Jacoby *et al.*, 1980). A linear measure of the maximum width of the frontal horns of the lateral ventricle to the maximum internal skull diameter (bifrontal/intracranial ratio) was also determined for each subject.

TABLE I
Correlation between cognitive measures and those of lateral ventricular size

	VBR	Bifrontal-intracranial ratio
MTS	-0.70	-0.61
DCT	-0.67	-0.55

All significant at $P<0.001$

TABLE II
Mean attenuation density in HU's and s.d. in different brain regions and analysis of variance

Region	Hemisphere	Patients with senile dementia (n = 48)	Normal elderly controls (n = 40)	F (d.f. = 1)	P ²
Cerebellum	L	42.24 ± 3.91	43.37 ± 4.54	2.47	NS
Cerebellum	R	42.77 ± 4.11	43.36 ± 3.88	0.73	NS
Pons		35.45 ± 4.41	37.29 ± 4.87	2.87	NS
Medial temporal	L	38.08 ± 5.11	37.43 ± 9.15	0.82	NS
Medial temporal	R	37.54 ± 5.23	39.59 ± 4.89	1.62	NS
Anterior frontal	L	39.90 ± 4.09	40.02 ± 3.71	0.18	NS
Anterior frontal	R	39.63 ± 4.24	39.24 ± 3.37	0.08	NS
Caudate	L	38.20 ± 3.86	38.89 ± 2.60	2.35	NS
Caudate	R	37.57 ± 4.73	38.47 ± 2.72	0.84	NS
Thalamus	L	38.28 ± 2.78	39.03 ± 1.80	1.16	NS
Thalamus	R	37.54 ± 2.96	37.83 ± 1.91	0.12	NS
Parietal	L	39.15 ± 2.85	38.84 ± 3.43	0.61	NS
Parietal	R	38.12 ± 2.70	38.73 ± 3.91	0.26	NS
Occipital	L	41.95 ± 3.44	42.55 ± 3.58	0.48	NS
Occipital	R	41.53 ± 3.54	42.28 ± 3.50	0.63	NS

1. NS Indicates not significant analysis of variance.

2. HU indicates Hounsfield Units.

Results

The mean age of the demented subjects (77.9 ± 8.4) did not differ significantly from that of the control group (75.0 ± 8.3). The preponderance of females was similar in both groups (38 of 48 vs 31 of 40).

Demented subjects performed significantly worse than normals both on the Mental Test Score (10.3 ± 5.8 vs 31.8 ± 3.0 , $P < 0.001$) and the Digit Copying Test (28.8 ± 22.7 vs 82.2 ± 34.3 , $P < 0.01$).

Ventricular size was larger in the demented patients than in the control subjects both as assessed by the VBR (18.7 ± 4.2 vs 9.5 ± 4.1 , $P < 0.001$) and by the linear bifrontal/intracranial ratio (38.7 ± 4.1 vs 31.9 ± 4.3 , $P < 0.001$).

Cognitive measures were found to correlate negatively with those of ventricular size when the total sample of normal controls and demented patients was examined but not for the separate groups (Table I).

Although attenuation density was generally lower in SDAT subjects this was not significant in any region when demented and normal subjects were compared (Table II).

Correlations between regional density measurements and cognitive tests were in general low and not statistically significant with the exception of those between the MTS and pontine density ($r = 0.31$, $P > 0.004$), MTS and left thalamic density ($r = +0.20$, $P > 0.03$) and between the DCT and density in the right occipital region ($r = +0.23$, $P > 0.04$).

Discussion

The finding that patients with SDAT have significantly larger lateral ventricles than a group of normal control subjects of a comparable age is consistent with reports by other workers (de Leon, *et al*, 1960; Jacoby & Levy, 1980; Brinkman *et al*, 1981; Gado *et al*, 1982). Cognitive measures were found to

FIG. 1. Scattergram of Mental Test Score (MTS) against ventricular-brain ratio (VBR) for normal controls and demented patients ($r = -0.70$, $P < 0.001$).

FIG. 2. Scattergram of scores on the Digit Copying Test (DCT) against ventricular-brain ratio (VBR) for normal controls and demented patients ($r = -0.67$, $P < 0.001$).

correlate with those of ventricular size only when the demented and normal control groups were amalgamated as was found by Jacoby & Levy (1980). Scattergrams are provided of scores on the cognitive measures against VBR for normal controls and demented patients combined (Figs 1 and 2). That there were few large or statistically significant correlations between regional attenuation densities and cognitive measures is in keeping with a report by Naguib & Levy (1982) who used the same EMI scanner but a different group of patients. Higher correlations between CT density and cognitive measures have been reported by other workers (de Leon *et al*, 1980) but this may reflect the use of a more advanced scanner or to differences in sampling technique of regions of interest. Unfortunately de Leon & George (1983) do not state what size area of each region of interest was sampled in their study.

The present findings do not suggest that patients with SDAT differ significantly from normal elderly with respect to CT mean attenuation density in any of the regions examined. Our findings do not, therefore, replicate those previously reported by Bondareff *et al* (1981) working with our group. He found significantly lower attenuation density bilaterally in the anterior frontal, medial temporal and caudate regions of a group of patients with senile dementia when they were compared with a group of normal elderly controls. We used the same EMI CT 1010 scanner and similar methodology to that of Bondareff *et al* (1981). It is not likely that the sampling of regions of interest differed greatly in that

the density measurements by the present investigators on the same scans correlated highly ($r=0.93$, $P<0.001$). Scanner drift does not appear to be a likely source of variation in that densities were not found to correlate with date of scan over a 6 month period and a plot of density readings from a phantom over time did not suggest any systematic drift. A possible, although speculative, explanation for the difference in findings of the present study and that of Bondareff *et al* (1981) might be that the samples of demented patients studied were not comparable. Whilst both studies selected patients whose symptoms conformed to the ICD 9 criteria for senile dementia they differed in that those patients in the present study whose blood pressure exceeded 100 mmHg diastolic or 160 mmHg systolic were excluded. The 25 scans used by Bondareff *et al* (1981) were selected from the series of 40 patients reported by Jacoby & Levy (1980). Although in this series patients with hypertensive disease were not included those with high blood pressure alone were deliberately not excluded. Jacoby & Levy (1980) reported 10 patients with silent infarcts and these were significantly more likely to have had a diastolic blood pressure greater than 100 mmHg. It is possible that were many of these patients with silent infarcts to have been included in the sample studied by Bondareff *et al* (1981) this may have predisposed the finding that the demented group had lower attenuation density in some regions, alternatively it may be that patients with raised blood pressure have different CT attenuation densities from those who are normotensive.

In conclusion, it would appear that attenuation density does not significantly differentiate senile dementia subjects from age-matched controls although this method appears to show differences within the dementia group in that low attenuation in the parietal regions is associated with a more rapid demise (Naguib & Levy, 1982; Colgan, 1985). Further studies should therefore concentrate on the use of this method to isolate subgroups with different clinical courses rather than attempting to employ it as a diagnostic procedure.

Acknowledgements

The authors wish to thank the staff of the Department of Radiology of the Maudsley Hospital for their cooperation and Nadine Morgan for typing the manuscript. The work was supported by a grant from the Special Health Authority of the Bethlem and Maudsley Hospitals to Professor Raymond Levy. Scans were read using an IVC 464 which had been reprogrammed by Mr R Baldy and was funded by a grant from the Medical Research Council to Professor W A Lishman.

Cognitive Functioning in Parkinson's Disease: In Relation to Prevalence of Dementia and Psychiatric Diagnosis

J. R. OYEBODE, W. A. BARKER, G. BLESSED, D. J. DICK and P. G. BRITTON

Forty-three neurologically and psychiatrically assessed patients with idiopathic Parkinson's disease (PD) underwent detailed cognitive assessment. Cognitive deficits typical of senile dementia of Alzheimer's type (SDAT) were found in 7% but the majority showed definite impairments not typical of SDAT. Cognitive impairment was significantly more likely in those with more severe PD symptoms. There was substantial agreement between psychiatric diagnosis and psychological picture of SDAT and some links were found between other diagnostic categories and nature of cognitive functioning. However, cognitive deficits were also found in two-thirds of patients with no psychiatric diagnosis.

The prevalence of dementia in Parkinson's disease has been a longstanding subject of speculation and investigation. It is recognised that it is important to have factual information on the issue for both theoretical and practical reasons, but it is also acknowledged that accurate information is extremely difficult to obtain. Recent reviews (Boller, 1980; Mayeux, 1982; Brown & Marsden, 1984) highlight the wide variation in estimates of prevalence from 20% to 81%.

There are a number of factors which may contribute to such a degree of variation, including the definition of dementia adopted, the means of assessing presence of dementia and the composition of the PD sample.

Definitions of dementia adopted in studies of PD patients have varied from an inclusion of all patients with evidence of cognitive impairment to a narrower definition more consistent with the DSM-III criteria for diagnosis of dementia (American Psychiatric Association, 1980). A useful definition is one whose operational criteria are clearly defined and which is narrow enough for useful theoretical conclusions to be drawn, e.g. for the purposes of the present study our interest is in the presence of a defined constellation of deficits seen as being typical of senile dementia of Alzheimer's type (SDAT).

The method of assessment needs to be able to distinguish changes due to dementia from those caused by other factors, including normal ageing, depression, acute confusional states and physical disability, all of which have an increased risk of being present in patients with PD.

Finally, aetiology of PD in the sample assessed needs to be clearly stated. The most useful group to study from a theoretical point of view are patients with idiopathic PD.

Aim

The central aim of the study reported here was to clarify whether there is an increased risk of patients with idiopathic PD having cognitive deficits typical of senile dementia of Alzheimer's type (SDAT). Secondary aims were to ascertain the proportion of patients with idiopathic PD having cognitive impairments not typical of SDAT; and to examine how the nature and severity of these deficits and impairments related to severity of PD, psychiatric diagnosis and types of treatment being received by subjects. Deficits typical of SDAT were defined as evidence of impairment in secondary memory (shown through impaired performance on a test of secondary memory or on an information/orientation scale); and of a significant decline in general intelligence (shown by a discrepancy of more than one standard deviation between current and pre-morbid intelligence).

Subjects

All patients with a diagnosis of idiopathic PD attending the Regional Neurological Centre, Newcastle General Hospital, between September 1981 and March 1985 were invited to participate in a research study on complications of PD. Two patients declined but a cohort of 81 was established

and all were assessed by neurologists and psychiatrists over a 3-year period to establish the severity of their PD as well as the presence of any degree of dementia or depression, or other significant psychiatric disorder.

Appointments were sent to 63 patients drawn from the cohort of 67 patients still living, for psychological assessment between July 1984 and March 1985. Twenty did not attend (two refused, five moved away, five had temporary ill health, four because of miscellaneous reasons, four for reasons unknown) and four were not sent appointments for practical reasons e.g. they were living a great distance from the hospital. The attenders comprised 21 women (mean age 63.6 years, range 59–77) and 22 men (mean age 66 years range 53–71 years). Their mean duration of disease was 14 years (± 13) and ratings on the Webster Parkinson Disability Scale (Webster, 1968) showed that at the time of psychological assessment 18 had mild impairment (Webster 0–9), 20 showed moderate impairment (Webster 10–19) and five showed severe impairment (Webster 20+). Of those with predominantly unilateral symptoms nine had left-sided disabilities and eight had right-sided disabilities.

All patients except one were receiving medication; (31 levodopa preparations; one bromocriptine, two anticholinergic medication and eight a

combined drug therapy). Three had had stereotaxic surgery.

Age-matched control subjects included spouses of patients and attenders at Newcastle Age Concern Pop-In. None had any severe physical disability or history of psychiatric illness.

Method

All control subjects and 35 patients were seen in a quiet, well lit room. Seven patients were seen at their place of residence and one during a short-stay hospital admission.

Administration of tests took between 45 and 90 minutes and subjects were given time to rest between tests as appropriate. An attempt was made to assess all patients in the areas listed below, with the exception of the visual-spatial imagery test which was administered to a subgroup of 13 patients.

Full descriptions of the tests are not given but brief notes give cogent information on why the tests were chosen for use with this population.

1. *Pre-morbid intelligence: New Adult Reading Test (NART)* (Nelson & O'Connell, 1978). This test has been standardised on British population samples up to age 70 and has proved to give valid results with patients diagnosed as demented.

2. *Current intelligence: Raven's Progressive Matrices (PM)* Standard or Coloured Version, as appropriate (Raven *et al* 1977). This was chosen in preference to the more

TABLE I

Number of patients with idiopathic PD showing normal and impaired performance on each of the series of tests

Area of cognitive functioning	Test	Criteria for impairment	% (n) results in normal range	% (n) results showing impairment
Intelligence	NART PM	Discrepancy of one s.d. or more between PM and NART	82% (28)	18% (6)
Information/orientation	CAPE I/Q scale	Score ≤ 7 shown in validation studies to be strong indicator of the presence of dementia	93% (37)	7% (3)
Primary memory	Digit-Span forwards	Below age-matched norms (i.e. < 5)	86% (33)	14% (5)
	Digit-Span backwards	Below age-matched norms (i.e. < 4)	72% (26)	28% (10)
Secondary memory	Two-choice verbal recognition	Below range scores of 12 age-matched control subjects	71% (24)	29% (10)
Retrieval from long-term memory	Benton Word Fluency Test (Total)	a) Below range scores b) Below 25%ile scores c) Above 25%ile scores of 12 age-matched controls	c) 22% (8)	a) 33% (12) b) 78% (28)
Visuospatial imagery	Block counting test	Below range scores 12 age-matched controls	31% (4)	69% (9)

TABLE II

Question raised of deficits (at least one mildly impaired score)	8	19
No cognitive deficits	1	2
Insufficient data	3	7

commonly used Wechsler Adult Intelligence Scale since movements are not required to complete the items and it is untimed. In addition, British norms are available up to age 89 years.

3. *Knowledge of current information/orientation: Clifton Assessment Procedures for the Elderly (CAPE) Information/Orientation Scale* (Pattie and Gilleard, 1979). This test has been validated against diagnosis of dementia and standardised on British samples over age 60 years.

4. *Primary Memory: Digit span* forwards and backwards. The standard subtest from Wechsler Adult Intelligence Scale (Wechsler, 1958) was used.

5. *Secondary Memory: 2 choice verbal recognition memory* The test used was an extended version of that described by Morris *et al* (1983) and found to be sensitive to memory deficits of patients with mild to moderate SDAT. The recognition format appears to be equally informative, yet it is less threatening to patients than a recall test.

6. *Retrieval from long-term memory: Benton Word Fluency Test* (Benton, 1968).

7. *Visuospatial imagery: modification of block counting test* from Stanford-Binet Intelligence Scale (Terman & Merrill, 1973). Each item requires mental reconstruction of a three-dimensional object from a line drawing and it thus tests an aspect of visuospatial functioning without requiring a motor response.

Results

All, or the majority of tests, were completed by 36 out of 43 patients with the remainder carrying out such tests as their disabilities and circumstances would allow. Table I shows results with regard to performance on each test and Table II gives the results in a manner related to the aims of the study.

A majority of patients showed deficits on the tests of retrieval from long-term memory (Benton Word Fluency Test) and visuospatial imagery (Block Counting Test).

On the word fluency test significant differences were found between patients and control subjects in the number of words produced on each letter and in total (see Table III). A number of perseverative intrusions (i.e. production

of a word from a previous letter category) were given by 10 (32%) of patients but no control subjects. There was no significant difference in the number of repetitions (i.e. of a word already given) the majority of subjects giving at least one repetitive response.

TABLE III
Average number of words recalled on each letter and in total on Benton Word Fluency Test

	<i>Letter 1</i>	<i>Letter 2</i>	<i>Letter 3</i>	<i>Total</i>
Age-matched Control subjects ($n=12$)	16.4	15.6	15.1	47.1
Idiopathic PD patients ($n=36$)	10.4	9.9	9.9	30.3
Significance of difference	$P<0.01$	$P<0.02$	$P<0.01$	$P<0.001$

On the test of visuospatial imagery control subjects scored significantly higher than the patient group (controls: average 12.5/14; patients: average 7.45/14; $t=3.75$, $P<0.01$).

In all other areas assessed, a minority of patients showed impairment in comparison with age-matched norms drawn from British standardisation studies, or control data.

Relationship of cognitive dysfunction to other measures

A significant, though fairly low, positive correlation was found between length of illness and severity of PD as measured by Webster scale ratings ($r=+0.35$; $P<0.05$). Those with mild symptom ratings were significantly less likely to show cognitive impairment than those with moderate symptom ratings—Webster score 0–9: 61% definite cognitive impairment; Webster score 10–19: 95% cognitive impairment; $\chi^2=4.6$, $P<0.05$). Of five patients with severe symptom ratings, two had deficits typical of SDAT and two had severe communication problems which limited assessment. The fifth showed mild deficits. There was a tendency for a greater proportion of patients who had a lengthy history to have more severe cognitive impairment in comparison with those with a short history but this trend was not significant.

As symptoms of PD became more severe there was a tendency for word fluency to be poorer ($r=0.3$; $P<0.1$). In unilateral cases, side of symptoms had no influence on cognitive deficits found.

The three patients who had undergone thalatomy all had severely depressed word fluency, an effect which has been shown to occur after bilateral ventral thalamic lesions. Effects of medication on cognitive functioning could not be isolated but two patients with a history of drug-induced confusional states showed specific cognitive deficits indistinguishable in character from the general sample.

The relationship between psychiatric diagnosis and psychological assessment is shown in Table IV. For the purposes of this study patients found at psychiatric

¹ Includes one patient with diagnosis of combined depression and mild cognitive deficits

assessment to have cognitive impairment are divided into two diagnostic groups. The first includes those with SDAT, the second includes those with mild or doubtful dementia and those given a diagnosis of dementia qualified as not typical of SDAT (mild or atypical cognitive impairment). Where a psychiatric diagnosis of SDAT was made this predicted that the patients would show SDAT deficits at psychological assessment. In all other psychiatric categories, the majority of patients showed specific cognitive impairments, this being also true where there was no psychiatric diagnosis though in this group over 33% were found to have no definite evidence of cognitive impairment.

The nature of cognitive impairment showed some significant differences between diagnostic groups. Those diagnosed at psychiatric assessment as having mild or atypical cognitive impairment showed a significant lowering of intelligence (NART: average 109.25, PM: average 94.625; $P < 0.01$) whereas neither the depressives nor those with no psychiatric diagnosis showed any change in average level of intelligence. Those with a diagnosis of depression produced significantly fewer responses on the third letter of the word fluency test (depressives: average 8.1; non depressives: average 11.4; $P < 0.05$).

However, deficits in information/orientation, secondary memory and total production of words in the word fluency test were equally likely whether psychiatric diagnosis was of mild or atypical cognitive impairment, depression or no disorder.

Characteristics of patients not seen

Among those patients who died before they could be psychologically assessed a greater number had severe PD and a greater number received a psychiatric diagnosis of dementia than among the sample seen: 9.3% of all patients given a comprehensive psychiatric assessment received a diagnosis of SDAT with a further 2.7% receiving a diagnosis of dementia (atypical). Among those who did not attend or were not sent an appointment a greater proportion had moderate symptoms of PD and fewer had mild symptoms, but the proportion in the various psychiatric categories of diagnosis did not differ from the sample seen except for a greater number of cases with combined depression and mild cognitive impairment.

Discussion

Prevalence of dementia

Deficits typical of SDAT were found in 7% (three) of the current sample. This figure is lower than any estimate reported prior to 1985 except for a rate of 0 found by Patrick & Levy (1922).

Brown & Marsden (1984) present clearly the reasons why figures produced in many past studies may overestimate the prevalence of dementia. When studies of only those with idiopathic PD were examined the reported prevalence rate fell to 24.5%; and a correction for the use of inappropriate assessment measures led them to suggest that the true prevalence may be 15–20%. Less (1985) recently re-worked data in seven studies to include only patients whose diagnosis of dementia complied with DSM-III criteria and produced figures between 7 and 15%.

Thus re-examination of previous studies to correct for composition of sample, criteria for diagnosis and use of inappropriate assessment techniques produces a dramatic lowering in estimated prevalence to a similar level to that found in the prospective study reported here.

Since Brown & Marsden's critique was published, two short reports of equally low figures (15% and 8%) of prevalence for dementia have been given in published letters (Lees 1985; Taylor *et al* 1985). Thus clear evidence is emerging that the true prevalence rate for a clinical picture of dementia of Alzheimer's type in PD is substantially lower than was previously thought.

Two further points concerning these conclusions need to be made. Firstly we re-emphasise that the definition of dementia adopted influences the prevalence rate found. The term dementia, even defined as strictly as in the DSM-III criteria has disadvantages where an attempt is being made to distinguish between different patterns of cognitive

impairment, since it leads to the assembling of a heterogeneous sample of cognitively impaired individuals.

Operational definitions, which group together individuals who are impaired in stated aspects of cognitive functioning are more informative in this respect, and may clarify distinctions in this situation between patients who at psychiatric assessment appear to have SDAT and those who are felt to have an 'atypical' dementia.

Secondly, in this study despite using an operational definition of cognitive impairment we have tied our definition to a neurological level of explanation by using the term SDAT which implies the presence of certain cognitive pathology. The underlying pathology, however, cannot be assumed since identical cognitive impairments may be due to differing underlying pathology. Perry *et al* (1985) recently found that the pathological changes in a group of clinically demented PD patients differed from those in patients having SDAT in the absence of PD.

We therefore conclude that a lower proportion of PD patients have impairments typical of SDAT than was previously thought; but that the level of prevalence is nevertheless above that expected in the population of this age. Kay *et al* (1970) reported a prevalence rate of 2.4% among their population sample aged 65–69 years. This increased level of prevalence does not necessarily imply an increased risk among PD patients of developing SDAT but may indicate that a number of patients show cognitive deficits usually associated with SDAT but in their case consequent upon other cortical changes that may occur as a complication of PD.

Prevalence of other types of cognitive impairment

The results of the present study emphasise that many PD patients with no global dementia face difficulties in cognitive functioning. Taylor *et al* (1985) and Lees & Smith (1983) also found that a majority of patients with idiopathic PD showed subtle cognitive deficits not amounting to dementia. Risk of cognitive dysfunction appeared to increase to some degree with length and severity of illness, confirming some past findings (reviewed by Mayeux, 1982) but being contrary to the view recently put forward by McCarthy *et al* (1985) that there is correspondence between incidence of cognitive deficits in early and late PD. This issue may only be clarified by a longitudinal study of a patient cohort.

Interlink between psychiatric and psychological assessment

The results of this study suggest that where a psychiatric diagnosis of dementia has been made, the

patient is also likely to show SDAT deficits at psychological assessment. However, in all other cases, degree of cognitive dysfunction is almost independent of psychiatric diagnosis. This is such that the patient who receives no psychiatric diagnosis is almost as likely to show definite impairments as the patient who receives a diagnosis of affective disorder or mild or atypical cognitive impairment.

The dissociation, however, is not complete since the nature of the cognitive dysfunction may vary in some respects. Where a psychiatric diagnosis of mild or atypical cognitive impairment is made it seems that the psychiatrist is responding to a decline in general intelligence in the absence of clear-cut memory impairment, but more subtle impairments in word fluency and secondary memory may pass unnoticed. It should therefore be useful during psychiatric assessment of a patient with PD to include a simple test of word fluency in the absence of a full psychological assessment of cognitive functioning.

Where a patient is depressed there may be typical cognitive deficits as a result of the depression but these do not account for all the impairment found among this diagnostic group.

Conclusions

Results are now emerging from a number of sources, including the present prospective study, to suggest that the prevalence of deficits typical of SDAT in PD is lower than was previously thought, affecting only 5–15% of patients. More subtle forms of cognitive impairment may be much more common but can be missed during psychiatric examination. Their nature and course needs to be clarified through longitudinal follow-up and clearly designed psychological investigations.

Interactions between Procyclidine and Neuroleptic Drugs Some Pharmacological and Clinical Aspects

J. S. BAMRAH, V. KUMAR, J. KRSKA and S. D. SONI

Procyclidine was administered to 25 chronic psychotic inpatients, stabilised on chlorpromazine, haloperidol or fluphenazine decanoate injection. We observed a significant reduction in mean serum levels of all three neuroleptic drugs which was reversed on stopping procyclidine and was inversely correlated with mean serum procyclidine levels. No significant alterations occurred on the BPRS scores or in serum prolactin levels throughout the study in any of the three groups. Possible mechanisms of this interaction and its clinical relevance are discussed.

Extrapyramidal side-effects are a frequent accompaniment of neuroleptic treatment and anticholinergic agents used to reduce these symptoms are the commonest form of medication concurrent to neuroleptic therapy (Johnson, 1983). Apart from the observation that anticholinergics may not be superior to placebo in the treatment of drug-induced parkinsonism (Brumlik *et al*, 1964; Mindham *et al*, 1972), it has also been claimed that their use can result in an exacerbation of psychosis (Stephens, 1967; Shader & Greenblatt, 1971; MacVicar, 1977), a delay in symptom improvement (Singh & Kay, 1975, 1979; Johnstone *et al*, 1983) and a worsening of tardive dyskinesia (Crane, 1973; Klawans & Rubovits, 1974).

The possibility that these effects may be due to alteration in the blood levels of neuroleptics has been the subject of many studies. The results, however, are by no means unequivocal. Rivera-Calimlim *et al* (1973, 1976), Loga *et al* (1975), Gautier *et al* (1977) and Morselli *et al* (1980) reported that co-administration of anticholinergic drugs resulted in lower blood levels of neuroleptics. In several other studies no differences were observed (El-Yousef and Manier, 1974; Hansen *et al*, 1979; Linnoila *et al*, 1980; Simpson *et al*, 1980; Johnstone *et al*, 1983) and an increase in chlorpromazine levels was found by Kolakowska *et al* (1976).

We re-examined our data from a study relating neuroleptic dosage to serum level in chronic schizophrenics (Krska *et al*, 1986), dividing patients into two groups according to whether an anticholinergic was prescribed. For most neuroleptics, there were no differences in the dose, serum level or in the serum level/dose ratio between the two groups. In patients

the two groups. In patients treated with fluphenazine decanoate, however, those patients receiving anticholinergics had significantly lower serum level/dose ratios than those on fluphenazine alone ($P=0.04$, Mann Whitney U Test).

This study was designed to investigate the effect of administration of an anticholinergic drug on neuroleptic blood levels and clinical parameters in patients stabilised on different antipsychotic agents. The neuroleptics studied were fluphenazine decanoate, as an example of a parenteral drug and chlorpromazine and haloperidol, both oral drugs, but with differing chemical structures and metabolism. Procyclidine was used as the anticholinergic drug and a method of measuring its serum levels was developed to establish compliance.

Method

Clinical procedures

Subjects

Male and female inpatients in Prestwich Hospital, diagnosed as chronically schizophrenic, who had no physical illness and had been stable on one neuroleptic for at least 4 weeks, were selected for the study. Of these 12 were receiving chlorpromazine, 12 haloperidol and nine fluphenazine decanoate.

Design of the study

(Fig. 1). The protocol was passed by Salford Health Authority Ethical Committee and was carried out between June 1983 and July 1984. Patients entering the study continued to receive the same dose of the neuroleptic on which they had been maintained for several weeks, or in

FIG. 1. Design of the study. Blood samples were collected every week; clinical assessments done at weeks 1, 2, 6 and 10.

most cases, months prior to the study. This dose did not change in any patient throughout the 10 weeks of the study. Procyclidine 5–15 mg/day (depending on the severity of extrapyramidal symptoms) was added to the neuroleptic therapy from the end of week 2 for exactly 4 weeks. It was then discontinued abruptly and the patients maintained on neuroleptic alone until the end of the study.

The only non-study drug administered was in patient no. 20 who received sulthiame 50 mg twice daily throughout. Blood samples were taken weekly for the whole 10 weeks and clinical assessments made on weeks 1, 2 (baseline), 6 (after 4 weeks of procyclidine) and 10 (4 weeks after stopping procyclidine). Occasional blood samples were omitted in a few patients for various reasons; where this was the case, it is noted in the legends to the figures.

Rating procedures

Psychiatric status was assessed using the Brief Psychiatric Rating Scale (BPRS) (Overall & Gorham, 1962) and extrapyramidal side-effects using the Extrapyramidal Scale (EPS) of Simpson and Angus (1970). Assessments were made prior to blood sampling on four occasions throughout the study. Each patient was assessed by the same rater throughout.

Biochemical procedures

Laboratory personnel responsible for measurements were blind to all treatments.

Neuroleptic levels

Serum levels of all neuroleptics were measured by the radioreceptor assay method (Krska *et al.*, 1986) using haloperidol as internal standard. The results are expressed in terms of 'neuroleptic units'.

Prolactin levels

Serum prolactin was measured by radioimmunoassay using a kit obtained from Chelsea Hospital for Women (Dovehouse Street, London). The precision of this method was 4.8% within assay and 6.2–8.2% between assay over the range 150–850 mIU/litre. Prolactin levels in nine

normal males and 14 females were 88–215 and 99–250 respectively.

Procyclidine levels

A method of measuring procyclidine in serum by antiparkinsonian radioreceptor assay was developed for this study, based on the method of Tune & Coyle (1980). Samples were assayed after precipitation of proteins so values obtained represent total drug (i.e. free and bound to serum proteins). Procyclidine was used for the standard curve and results are expressed as nmol/litre. Recovery of procyclidine from spiked serum was $95 \pm 13\%$, $95.5 \pm 12.4\%$ and $98.6 \pm 7.9\%$ for concentrations 500, 1000 and 1500 nmol/litre respectively.

Statistical analysis

All data were divided according to neuroleptic drug and subjected to analysis of variance for differences among week numbers. If this was significant, paired *t*-tests were performed for selected week numbers. Relationships between variables were studied by Pearson's product moment correlations.

Results

General

Of the 12 patients who were in the chlorpromazine group, two dropped out because of uncooperation or aggression. One patient receiving haloperidol was excluded because of antiparkinsonian side-effects; one patient in the fluphenazine group refused to give blood samples and a second patient developed an increase in psychotic behaviour before the introduction of procyclidine; both were excluded. The demographic data for the remaining patients (Table I) showed no significant differences in any of these parameters between groups.

When the samples were analysed, one patient in the chlorpromazine group (no. 10) had very low neuroleptic levels and was judged to have been non-compliant. One patient in the haloperidol group (no. 21) had detectable

1. Dose in mg/week for fluphenazine decanoate

2. Data excluded from analysis as patient was found to be noncompliant

3. Data from weeks 7-10 excluded from analysis as procyclidine not discontinued

4. Patient received sulthiame 50 mg twice daily throughout the study

5. Data excluded from analysis as patient had detectable procyclidine levels throughout the study

6. Data excluded from analysis as no procyclidine was detected in any sample

procyclidine levels. All three patients were excluded from statistical analysis.

Serum neuroleptic levels

The administration of procyclidine resulted in a significant fall in serum neuroleptic levels in 19 of the remaining 25 patients. In three patients on chlorpromazine and two on haloperidol there was little change in the neuroleptic level. One patient in the chlorpromazine and another in the fluphenazine group had higher levels (+14% and +27% respectively) whilst also receiving procyclidine.

In the chlorpromazine group, the mean neuroleptic level fell gradually from the baseline level after initiation of procyclidine, reaching a minimum after 3 weeks. The level then increased again, despite continuing procyclidine and continued to rise back to baseline after stopping the drug. In haloperidol treated patients, the mean neuroleptic level

fell significantly after only 1 week on procyclidine and remained low until the drug was stopped, after which the level returned to baseline. The pattern in patients on fluphenazine was similar to haloperidol; mean neuroleptic levels were low on all 4 weeks of procyclidine treatment, then returned to baseline after stopping the drug. The mean neuroleptic levels of all groups are shown in Figs 2, 3 and 4.

Prolactin levels

Prolactin was elevated in six out of nine patients on chlorpromazine, five out of six on fluphenazine and all on haloperidol. Among the patients on haloperidol and fluphenazine, those who had high neuroleptic levels tended to have higher prolactin levels but this was not the case for chlorpromazine. In most patients, prolactin varied only slightly from week to week, but in a few patients large swings were seen. There were no overall trends in prolactin

FIG. 2. Effect of procyclidine, administered from weeks 3 to 6, on serum neuroleptic level, serum procyclidine level and extrapyramidal symptom score in nine patients receiving chlorpromazine. Points are mean $\pm$ standard error.

levels and no significant differences between weeks in any of the three treatment groups. Mean prolactin levels were not related to mean neuroleptic levels.

Serum procyclidine levels

Procyclidine was detected in weeks 3 to 6 in all patients except one from the fluphenazine group whose data were excluded from analysis. The levels were fairly constant within each patient and declined gradually on stopping the drug. Levels varied widely between patients and were not related to the daily dose of procyclidine. Mean neuroleptic levels inversely correlated with mean procyclidine levels for all three groups: chlorpromazine $r = 0.805$, $P < 0.005$;

haloperidol $r = 0.907$, $P < 0.0005$; fluphenazine $r = 0.773$, $P < 0.01$. Mean procyclidine levels for all groups are shown in Figs 2, 3 and 4.

Clinical state

The three groups were the same with respect to clinical state as measured by the BPRS score before procyclidine was given (week 2). There were no changes in the mean BPRS score in any group after 4 weeks on procyclidine (week 6) or after a further 4 weeks on neuroleptic alone (week 10). However, in one patient (no. 12) there was a substantial fall in the total BPRS score (9 points) at week 6, which was due to a reduction in positive symptoms. A second patient (no. 13) became considerably more psychotic (increase of

FIG. 3. Effect of procyclidine, administered from weeks 3 to 6 on serum neuroleptic level, serum procyclidine level and extrapyramidal symptom score in ten patients receiving haloperidol. Points are mean $\pm$ standard error.

FIG. 4. Effect of procyclidine administered from weeks 3 to 6 on serum neuroleptic levels, serum procyclidine level and extrapyramidal symptom score in six patients receiving fluphenazine decanoate. Points are mean $\pm$ standard error.

15 points on the BPRS score) whilst receiving procyclidine. Both patients were in the haloperidol group. These changes were reversed after stopping procyclidine; no further changes in neuroleptic dose were required.

Side-effects

There were no significant differences in the EPS scores between groups before procyclidine treatment was started. In all three groups the score was greatly reduced after 4 weeks on the anticholinergic ($P < 0.05$ at least, paired *t*-test). However, only in the haloperidol group did the score return to its previous level 4 weeks after stopping procyclidine. In patients receiving either chlorpromazine or fluphenazine, EPS scores remained lower than at week 2 despite the return of the neuroleptic levels to baseline and the absence of detectable procyclidine in the serum. Mean EPS scores are shown in Figs 2, 3 and 4.

One patient in the fluphenazine group had an apparent increase in tardive dyskinesia during procyclidine treatment

which had improved by 1 week after its discontinuation. As no rating scales for tardive dyskinesia were performed this effect was not quantified.

Discussion

The main finding of our study is that anticholinergic antiparkinsonian medication significantly reduces the serum levels of neuroleptic drugs. This is in agreement with the studies of Rivera-Calimlim *et al* (1973, 1976) and Loga *et al* (1975). Discontinuation of procyclidine resulted in a reversal of this effect on neuroleptic levels. This is also in keeping with the results of Gautier *et al* (1977) and Morselli *et al* (1980). Although control groups were not included in our study, several factors suggest that these changes were not due to either temporal variation or placebo effects. Patients entered the study at different times, independently of their neuroleptic treatment; it is therefore unlikely that all would have had a change in serum level at the same time from any other cause. The changes in serum levels are related temporally to both administration of procyclidine and to measurable levels of this drug in serum but not to the dose of procyclidine as reported by Chouinard *et al* (1977).

Despite the overall effect of procyclidine on neuroleptic levels, there were no differences in both the mean percentage fall in serum level and in the proportion of patients showing a fall between the three neuroleptic groups. These differences may help explain the conflicting results found by other workers such as El-Yousef & Manier (1974) and Hansen *et al* (1979), who showed no changes in serum levels of butaperazine and perphenazine respectively.

In the chlorpromazine group, only five out of nine patients had reduced serum levels, three showed no changes and one had an increased level while receiving procyclidine. Similar observations have been reported by Rivera-Calimlim *et al* (1976), who found three of 15 patients had higher chlorpromazine levels while on benzhexol and by Simpson *et al* (1980), whose patients had lower, higher or unchanged levels. A significant difference in mean chlorpromazine levels did not emerge until the third week of procyclidine therapy, which is similar to the results obtained by Loga *et al* (1975) using orphenadrine. This is in contrast to the lack of change after 15 days in the study reported by Simpson *et al* (1980) and an increase in levels found by Kolakowska *et al* (1976) after 7 days of benzhexol.

The interaction of anticholinergic drugs with haloperidol has been studied rather less than with chlorpromazine. Eight out of ten patients had a dramatic reduction in serum level which was

maintained throughout the 4 weeks of procyclidine treatment. A reduction in haloperidol serum levels in two out of three patients when given benzhexol has also been reported by Morselli *et al* (1980). However, Linnoila *et al* (1980) in a rather complicated study, found no differences in serum levels of either haloperidol or thioridazine in behaviourally disturbed, mentally retarded patients whether or not they also received biperiden. Studies of large populations of neuroleptic-treated patients with or without long-term anticholinergic drugs, such as those of Forsman & Ohman (1977) and Itoh *et al* (1980) cannot be directly compared to the results of the present study. Nevertheless, the lack of differences in serum levels between these groups of patients, which we have also found, may suggest that tolerance develops to this effect of anticholinergics.

The reduction in fluphenazine serum levels in five out of six patients was surprising because of the depot characteristics of fluphenazine decanoate. However, lower relative serum levels had been found previously in patients on long-term anticholinergic drugs. We have been unable to find any published data with which to compare these findings. Although Hansen *et al* (1979) did find that intravenous biperiden did not affect the blood levels of intramuscularly administered perphenazine, this is not comparable to longer-term anticholinergic administration.

Our results are particularly interesting with regard to the possible mechanism(s) by which anticholinergic drugs could lower neuroleptic levels. The reduction in gastric and intestinal motility caused by these drugs is dependent on many factors but may lead to prolonged intestinal transit time. In the case of chlorpromazine, this could result in increased intestinal metabolism and consequently reduced absorption (Rivera-Calimlim, 1976). Since the serum levels of a parenterally administered drug (fluphenazine) were also lowered by the anticholinergic in our study and the patterns of reduction in neuroleptic levels were more or less similar in the three groups, effects on gastric motility may be only of minor importance in the interaction. The induction of liver metabolising enzymes has been proposed as a possible mechanism (Loga *et al*, 1975) and orphenadrine has been shown to be a powerful enzyme inducer both in animals (Conney and Burns, 1959; Conney *et al*, 1960) and in man (Loga *et al*, 1975). Procyclidine may have a similar effect, which at least in haloperidol and fluphenazine treated patients, significantly alters serum neuroleptic levels within a week.

In the majority of patients, prolactin levels remained unaltered throughout the study, indicating

that dopaminergic function in the tubero-infundibular pathway is not affected by anticholinergic agents. Other workers have also found these drugs to have no effect on serum prolactin, both in patients (Kolakowska *et al*, 1976; Lindholm *et al*, 1978; Johnstone *et al*, 1983) and in normal volunteers (Halbreich *et al*, 1980). On the other hand, Lal *et al* (1979) showed that benztropine slightly increased prolactin response to haloperidol in normal volunteers, while de Rivera *et al* (1976) found that some chronic patients on neuroleptics and anticholinergics had higher prolactin levels than patients on neuroleptics alone. Our present data do not support these findings. However, in two groups of 25 patients on chlorpromazine, haloperidol or fluphenazine decanoate, matched for sex and dose of neuroleptic, we found the group which was receiving anticholinergic drugs did have higher serum prolactin levels (unpublished data). We feel the data from our present study are more likely to reflect the true effect of anticholinergic drugs on prolactin, since each patient acts as his own control, thereby eliminating the large interpatient differences which occur in the prolactin response to neuroleptics.

The adverse effects of anticholinergic drugs on psychotic symptoms found by many workers in acute patients (Hanlon *et al*, 1966; Singh & Smith, 1973; Singh & Kay, 1979; Johnstone *et al*, 1983) were not evident in the present study. Only one patient showed clinical deterioration during procyclidine administration and this was not associated with any marked changes in neuroleptic levels. Other studies involving similar, chronically ill patients in hospital also report no adverse clinical effects of anticholinergics (Kolakowska *et al*, 1976; Gautier *et al*, 1977; Simpson *et al*, 1980). Overall, this would suggest that effects such as delay in symptom improvement are more significant in the acute population.

All patients had a reduction in EPS score during procyclidine treatment. Discontinuation of procyclidine led to a return of extrapyramidal symptoms in only two patients on fluphenazine and five on haloperidol, and in only one of these was it found necessary to reinstate therapy. This observation is in agreement with studies of Orlov *et al* (1971) and McClelland *et al* (1974) and supports the recommendation that antiparkinsonian drugs should not be routinely prescribed with neuroleptic therapy (DiMascio & DeMirgian, 1970).

An increase in tardive dyskinesia seen in one patient appeared to be related to procyclidine, as the symptoms were reduced when the drug was discontinued. This effect of anticholinergics has been reported in the literature (Klawans & Rubovits, 1974).

In conclusion, our results show that procyclidine causes a significant reduction in the neuroleptic levels in chronic psychotic patients, without any significant adverse clinical effects. This reduction is inversely proportional to the serum procyclidine level, but is unrelated to the dose. The findings in our study suggest that the effect is due to enzyme induction by procyclidine, which would support the findings of delayed symptom improvement in acute patients treated simultaneously with neuroleptics and anticholinergics. Prolactin levels were not found to be affected by procyclidine. However, the drug did significantly alleviate extrapyramidal symptoms, which did not recur in the large majority of patients on discontinuation. This implies that antiparkinsonian drug administration is, in general, unnecessary with chronic neuroleptic therapy, but that adverse clinical effects are not as important as in acute patients.

The Epidemiology of Deliberate Self-harm The Ibadan Experience

A. O. ODEJIDE, A. O. WILLIAMS, J. U. OHAERI and B. A. IKUESAN

In a 6-month prospective study of the three main general hospitals in Ibadan, Nigeria, 39 cases of deliberate self-harm were reported out of a total 23, 859 subjects attending the sections of hospital studied. Thirty (76.9%) were under 30 years of age and 36 (86.3%) were under 34 years of age. The male to female ratio was 1.4.1: more than half of the population (51.3%) were students and 25.6%, manual workers. The methods used were mainly ingestion of chemicals (24 patients) and psychotropic drugs (11 patients). Disturbed interpersonal relationships, especially with parents, were mainly found to have motivated the acts. The implications of these findings are discussed.

In the last three decades, reports on the epidemiology of deliberate self-harm (DSH) in Western European and North American countries have shown many similarities (Weissman, 1974). Studies found that most subjects are aged between 20 and 30 years; there are more females than males involved; also more single persons and more persons from the lower social classes; self-medication is the most common method of self-harm, and depression is the most common diagnosis (Edwards & Whitlock, 1968; Aitken *et al*, 1969; Stanley, 1969; Birtchnell, 1970; Hetzel, 1971; Jacobson & Tribe, 1972; Murphy, 1972; Patel *et al*, 1972; Weissman *et al*, 1973; Whitehead *et al*, 1973). Moreover DSH occurs quite frequently in the context of recent interpersonal conflicts (Ellis *et al*, 1966; Venkoba, 1971); and the intensity of hopelessness in depression correlates with suicide intent (Pierce, 1977; Dyer & Kreitman, 1984).

From the few reports on DSH in Nigeria, the prevalence rate ranged from 1 to 7 per 1 000 000; males predominated and major psychiatric disorders were found to be associated with the act (Asuni, 1967; Eferakeya, 1984). Regarding the methods used for DSH, Asuni (1967) found physical self-harm (slashing of the throat etc) to be more common, although a more recent report showed that the ingestion of psychotropic drugs and chemicals was more prevalent (Eferakeya, 1984).

While both studies shed some light on the epidemiology of DSH in Nigeria, Asuni (1967) was unable to interview most of his cases and Eferakeya (1984), in using a retrospective design, limited the extent of the information obtainable. Yet, more than before, the frequency of reports in the news media of fatal and non-fatal DSH suggest an increase in its prevalence in Nigeria.

The need for more current epidemiological information on the subject prompted the present study, which is part of a larger study of fatal and non-fatal DSH in Ibadan. Our operational definition of a case was based on an episode of non-fatal, deliberate self-harm by means of physical injury, drug overdosage or poisoning carried out in the knowledge that it was potentially harmful and in the case of drug overdosage, that the amount taken was excessive (Morgan *et al*, 1975).

Method

The study was conducted in Ibadan, Nigeria. Ibadan, the capital of the present Oyo State of Nigeria is one of the largest cities in Africa. It is a sprawling city, with a projected population from the latest census, of 1.5 million people of the Negroid race. It is located about 150 km from Lagos, the capital of Nigeria. Within the city, health services are provided by government and private institutions. However, our preliminary study of the private practitioners in this city revealed that cases of DSH are hardly ever referred to such health services but to government specialist health institutions (unpublished data). This observation guided us in selecting the three main general hospitals in the city for the study. These are the Adeoyo State Hospital, Ring Road Specialist Hospital (both controlled by the Oyo State Government) and the University College Hospital (a Federal Institution). The areas of the University College Hospital covered throughout the study were the accidents and casualty or emergency sections and, medical and surgical inpatient services. At the State hospitals, the accident and emergency sections only were studied.

Patients population

All patients who fulfilled the operational definition of DSH and attended the above-mentioned sections of these

hospitals over a 6-month period (August 1984 to January 1985) were included in the study.

Interview procedure

A questionnaire was designed to collect information in the following areas; demographic data, reasons for deliberate self-harm, the method used, hospital diagnosis, psychiatric diagnosis, previous history of physical or mental illness, life events preceding the incident, history of substance abuse and treatment outcome. Experienced nursing sisters and a psychologist administered the questionnaire to the patients. Prior to the commencement of the study, the interviewers were trained in the use of the questionnaire and their joint interview ratings reached a satisfactory level of reliability before the main project started.

The interviewers ensured that the patients were interviewed as soon as possible after they had recovered from the major adverse effects of the attempts (usually within 24–72 h). The information obtained from the interviews were not made available to the physicians responsible for the patients' treatment or the psychiatrist consulted to assess the patient.

Apart from the questionnaire designed specifically for this project, the supplementary classification section of the International Classification of Diseases, ninth edition (ICD-9) was used to standardise the diagnosis given by the hospital doctors in non-psychiatric divisions of the hospital. Also, the clinical psychiatric diagnosis was based on Section V of the ICD-9 using the WHO glossary of definition of symptoms.

The data collected was manually analysed; *t*-test and *z* scores were used for test of significance with $P < 0.05$ as the level of statistical significance.

Results

Population studied and rate of deliberate self-harm

During the 6 months of the study, the total number of patients attending the accident and emergency units of the Adeoyo State Hospital and the Ring Road Specialist Hospital was 13 368. In the same period, 10 491 patients attended either the accident and emergency unit or were admitted to non-psychiatric wards of the University College Hospital, Ibadan. The 6-month incidence rate of DSH for the 1.5 million population of Ibadan was calculated to be 2.6 per 100 000. Of these, 39 patients were cases of deliberate self-harm; 18 of these 39 patients were seen at the State hospitals while 21 reported at the University College Hospital. On all the variables, we found no statistical difference between the population of State hospitals and that of the University College Hospital.

Age distribution

The mean age was 23.3 ± 7.3 years, median 21 years. There were 23 males and 16 females, the male to female ratio being 1.4:1. The male mean age was 24.8 ± 7.3 years. The female mean age was 21.1 ± 7.2 years. There was no statistical difference in age between the sexes ($t = 1.6$; $P > 0.05$; d.f. = 37). Thirty-three (84.61%) of the 39 patients were aged between 15 and 34 years. When the cohort was divided

into age groups, the peak of DSH (11 of 39, i.e. 28.2%) was in the age group 15–19 years.

Religion

Twenty-six (66.67%) of these patients were Christians whereas 13 (33.33%) were Muslims. The ratio of Christians to Muslims is therefore 2:1. This is in spite of the fact that Ibadan is mostly populated by Muslims.

Occupation

When the 39 patients were classified according to their occupations, 20 (51.3%) were students, 10 (25.6%) were manual workers, four (10.3%) were semi-skilled workers, three (7.7%) were skilled workers while only two (5.1%) were unemployed. Of the 20 students, 11 were females (i.e. 68.8% of the total 16 females) and nine were males (i.e. 39.1% of the total 23 males). There were more manual workers among the males than the females (39.1% and 6.3% respectively).

Marital status

Twenty-eight (71.8%) patients were single, ten (25.6%) were married, while only one (2.6%) was divorced.

Sibling position

In three patients, the sibling position was not stated by the interviewers. Of the remaining 36 subjects 18 (50%) are first borns; 25 (69.4%) of all patients are either first or second borns; only three (8.3%) had sibling position above fourth. There were no last borns.

Methods used in DSH

Table 1 shows the methods of deliberate self-harm used. Thirty-six (92.3%) of the thirty-nine patients used solid or liquid substances; 24 (61.5%) used non-ingestant chemicals amongst which insecticides, battery water and gamallin-20 were the most common. A total of 12 (30.8%) of the patients used psychotropic drugs, with diazepam being the commonest. The females showed a tendency to use a wider variety of psychotropic drugs than the males. Only three (7.7%) of the patients used physical means, namely, cutting throat with a blade (one case), setting one's self on fire (one case) and jumping from a height (one case).

Diagnoses

Acute reaction to stress was the diagnosis in 16 (41%) of the 39 cases. Five (21.7%) males and eleven (68.8%) females had this diagnosis. The diagnosis of acute reaction to stress was significantly more common ($P < 0.05$) among females than males. Ten (25.6%) cases were diagnosed as reactive depression; among these were seven males and three females. Four patients (10.3%) had a diagnosis of adjustment reaction. Other diagnoses are depressive psychosis, schizophrenia (two cases each, all males), sexual deviations (two cases, one male, one female); and psychic factors associated with other diseases (one case each, both males). Only in one subject was there insufficient information to make a psychiatric diagnosis based on the ICD-9.

Reasons for deliberate self-harm

Disturbed relationship with parents accounted for eight cases (20.5%); interpersonal discord with significant others, excluding spouses six cases (15.4%); marital discord, five cases (12.8%); frustration or shame resulting from failure in examinations, eight cases (20.5%); disappointment due to unwanted pregnancy, one case (2.6%); being reproached for impregnating a girl, two cases (5.2%); mental illness, five cases (12.8%); unresolved physical illness, unemployment, job dissatisfaction and financial problem, one case each.

Outcome of treatment

Seventeen (48.6%) of the 39 patients were referred to the psychiatrists while 15 (38.5%) were discharged home without any planned follow-up or even referral to psychiatrists. One patient (2.6%) was transferred to a peripheral, non-psychiatric hospital.

Fatal deliberate self-harm patients

Five patients died, three females (ages 15, 15, 16 years) and two males (aged 21 and 26 years old). All three females and the younger male had interpersonal conflicts with their parents, while the remaining male was unemployed. None of them took psychotropic drugs. Apart from the female who poured kerosene on herself before setting herself ablaze, the other four cases used non-ingestant chemical agents namely caustic soda, battery water, gamallin-20 and insecticide.

Discussion

Our results support some of Eferakeya's (1984) previous observations that a large proportion of DSH are students under the age of 30, and that males predominate. This is in contrast to findings in developed countries. However, the DSH incidence rate of 2.6 per 100 000 found in this study falls within the range previously reported. A more extensive epidemiologic study is therefore required to test the hypothesis that DSH is on the increase in Nigeria.

In addition, this is the first prospective study of DSH in this part of the world for 20 years. The strong association found between DSH and the diagnosis of acute reaction to stress in females has not been previously reported and one of the contributing factors is the diminishing social and emotional support for women in the face of rapid urbanisation, severe socio-economic constraints and cultural changes.

The prospective design of this study gave us the opportunity to explore the motives for deliberate self-harm. Disordered interpersonal relationships, especially between the patient and a significant person in his/her life stand out prominently as a causal factor. Such significant persons were invariably parents, spouses or very close associates

TABLE I

such as boyfriends. This finding agrees with the observation that distress drives people to self-poisoning acts and that distress is not the exclusive preserve of the mentally ill (Kessel, 1965). Morgan *et al* (1975) also found a high degree of psychological distress in the cases of attempted suicide that he studied. From our present report, acute stress reactions, with feelings of hostility and hopelessness rather than specific psychiatric disorders seem to account for most of the acts. This supports current reports of the association of hostility with suicidal attempts (Weissman *et al*, 1973; Hetzel, 1971; Dyer & Kreitman, 1984).

The finding of a high ratio of fatal to non-fatal DSH (1:7:8) is considerably higher than the ratio of 1:47 reported by Eferakeya (1984). In this study, 66.7% of the subjects used non-ingestant chemicals as opposed to 20.4% in Eferakeya's study; in addition four of the five subjects who died, ingested chemicals. The high fatality can be accounted for by the method employed and inadequate medical resources for resuscitation and management of complications after the attempt. Most of our patients committed their attempts impulsively. None of them had made previous attempts and factors related to high suicidal intent (Gelder *et al*, 1984) were absent apart from the predominant use of dangerous methods.

It is noteworthy that 50% of our cohort were first borns. Though the small size of the population would not permit a categorical statement, it is our impression that the adult role which young persons are expected to play prematurely in the Nigerian culture (such as being responsible for the stressful socio-economic and moral needs of their younger siblings) contribute to the sense of failure and frustration when not able to cope with these demands. This observation supports Cochrane's (1975) view of the role of stress in the lives of DSH patients.

One of the implications of the findings and observations reported in this paper is the need for further research into the epidemiology of DSH in Nigeria with a view to identifying factors that contribute to its apparent increasing prevalence. It is also essential that we develop better methods of preventing it and reducing the high fatal outcome.

Comparison of the Nutritional State of New and Long-term Patients in a Psychogeriatric Unit

A. GREER, D. H. McBRIDE and A. SHENKIN

Nutritional deficiencies have been implicated in the pathophysiology of various mental disorders. Life in Institutions has been associated with development of nutritional deficiencies, the elderly being most at risk especially those with senile dementia. In this study nutritional status, particularly vitamin and essential mineral status was assessed in a group of 64 new admissions to a psychogeriatric unit and 49 long-term patients.

The results indicated that psychogeriatric patients were at risk of experiencing nutritional deficiencies and those with senile dementia were likely to have more abnormalities than those with functional illnesses. Those patients in long-term care would appear to have a better nutritional state than those on admission.

Nutritional deficiencies have been implicated in the pathophysiology of various mental disorders. Hunter *et al* (1967) have reported two cases of patients presenting with psychiatric disorders, one with depressive symptoms, the other with psychotic symptoms and personality change, who had low levels of vitamin B₁₂ which when treated resulted in a marked improvement in their mental state. Thiamine (vitamin B₁) deficiency has long been associated with Wernicke's encephalopathy which if untreated may lead to Korsakoff's psychosis. More recently Carney *et al* (1982) have associated affective changes with vitamins B₂ and B₆ deficiency.

Folic acid has long been known to be associated with psychiatric disorders. Strachan & Henderson (1967) described an improvement in the mental state of two patients with dementia following folic acid treatment and indeed Reynolds (1967) has suggested that many of the symptoms of dementia may be the result of folic acid deficiency rather than the dementia causing the folic acid deficiency. More recently studies have shown a high incidence of folic acid deficiency in geriatric patients (Sneath *et al*, 1973, Vir & Love 1979) and those with senile dementia are particularly at risk (Sneath *et al*, 1973).

Studies on both acute and chronic psychiatric patients have indicated that zinc deficiency is associated with senile dementia, schizophrenia and chronic alcohol abuse (Srinivasan, 1984) and other trace elements such as vanadium, lead and aluminium are topical areas of research. Institutional care has been implicated as a cause of malnutrition and has been highlighted by Anderson (1968) and Bender (1984).

Thus three risk factors which predispose to malnutrition are:

- (1) the elderly
- (2) those with senile dementia
- (3) those in long-term care.

It was therefore the purpose of this study to assess the nutritional status of new admissions to a psychogeriatric unit, looking for any differences between those suffering from dementia and those with functional illnesses and to compare them with long-term patients.

Method

Group 1 consisted of 64 new admissions, median age 78 years (range 65-92 years). They were divided into those with functional illnesses, Group 1a (*n*=21) and those with dementia, Group 1b (*n*=43). Group 2 consisted of 49 long-term patients, median age 79 years (range 67-91 years) who had been in hospital for a minimum of 1 year, median 4.5 years (range 1-52 years). Group 2 was also divided into those with functional illnesses, Group 2a (*n*=12) and those with dementia, Group 2b (*n*=37).

Blood from each patient was assessed within 72 h of admission for serum albumin, transferrin, calcium, phosphate, magnesium, iron, zinc, copper, vitamins A, E, C, B₁₂, folate and red cell folate. Vitamins B₁, B₂ and B₆ status was assessed by red cell enzyme studies. Other routine haematological and biochemical studies were also carried out. Reference normal values were derived from 100 elective admissions for orthopaedic surgery, with no evidence of organic disease or nutritional deficiency. Where age was found to affect the reference range, reference values were derived from 40 patients aged 51-80 (median 62). Groups were compared using Wilcoxon Rank Sum Tests for non-paired data and χ^2 analyses.

TABLE I
Vitamin and mineral results in Groups 1 and 2

	Reference range	Group 1			Group 2		
		n	median	range	n	median	range
Vitamin A	1.0–3.5 $\mu\text{mol/litre}$	63	1.8	0.9–3.8	48	2.2	1.1–6.4**

** $P < 0.002$

1. High levels of activation of rbc enzymes are indicative of poor vitamin status.

Results

Comparison of Group 1 (acute) with Group 2 (chronic)

Significant differences were found between the two groups with respect to vitamin B₁ and B₆ status, red cell folate, serum retinol, vitamin E and copper. The results are shown in Table I. With the exception of copper, the results indicate poorer status in Group 1.

No significant differences were observed between the groups with respect to vitamin B₂ status or serum vitamin B₁₂, folate, vitamin C, magnesium, zinc, iron, albumin or transferrin.

There was also a significant difference in the number of patients in each group who had abnormalities of their vitamin or essential mineral status with Group 1 having more patients with abnormal results.

In Group 1 abnormally low values were found in 7 out of 58 patients for vitamin B₂ status, 13 out of 55 patients for serum vitamin C, 17 out of 61 patients for serum zinc and 13 out of 59 patients for serum iron. In Group 2 the respective frequencies were 0 out of 49, 5 out of 38, 10 out of 48 and 6 out of 42 patients. The difference in frequency for vitamin B₂ status was significant ($P < 0.01$, χ^2 test).

Comparison of Groups 1a (acute functional), 1b (acute dementia), 2a (chronic functional) and 2b (chronic dementia)

There was no significant difference in the number of patients in each subgroup with abnormally low values although the trend was for the dementia subgroups to have more patients with abnormally low values. Thus the percentage of patients in each subgroup with one or more abnormalities was 57% in Group 1a, 79% in Group 1b, 33% in Group 2a and 62% in Group 2b. The mean number of abnormalities for each patient was 1.28 in Group 1a, 1.8 in Group 1b, 0.67 in Group 2a and 1.08 in Group 2b.

Comparison of Groups 1a (acute functional) and 1b (acute dementia)

On admission Group 1b had significantly lower serum concentrations of zinc and vitamin B₁₂ than Group 1a. Also in Group 1b abnormally low values were found in 12 out of 39 patients for serum iron, 14 out of 40 patients for serum zinc, 7 out of 35 patients for serum vitamin C and 6 out of 39 patients for vitamin B₂ status. The respective frequencies in Group 1a were 1 out of 20, 3 out of 21, 6 out of 20 and 1 out of 19 patients. The difference in frequency for serum iron was significant ($P < 0.02$, χ^2 test).

Comparison of Groups 2a (chronic functional) with 2b (chronic dementia)

There was no significant difference between Groups 2a and 2b with respect to their vitamin and essential mineral status but there was a significantly higher number of patients in Group 2b (10 out of 36 patients compared with 0 out of 12) who had abnormally low values for serum iron ($P < 0.05$, χ^2 test).

Comparison of Groups 1a (acute functional) with 2a (chronic functional)

Comparing Group 1a with Group 2a, significantly more patients in Group 1a had abnormally low vitamin B₁ status (3 out of 11 patients compared with 0 out of 12). Otherwise there were no differences between the groups.

Comparison of Groups 1b (acute dementia) with 2b (chronic dementia)

Group 2b had significantly higher levels of vitamins A, B₁, B₂, B₁₂, and red cell folate than Group 1b as shown in

TABLE II
Significant differences between acute and long stay demented patients

	Group 1b			Group 2b		
	n	median	range	n	median	range
Vitamin A ($\mu\text{mol/litre}$)	42	1.7	1-3.2	36	2.1	1.1-6.4*
Vitamin B ₁ (% activation)	28	13	1-27	37	7	1-25*
Vitamin B ₂ (% activation)	39	15	1-110	37	10	1-54**
Vitamin B ₁₂ ($\mu\text{g/ml}$)	30	247	38-480	35	313	99-600**
Red cell folate (ng/ml)	30	176	76-795	35	201	106-708**

* $P < 0.02$

** $P < 0.05$

Table II. Group 1b also had significantly more patients with abnormally low vitamin C levels (7 out of 35 patients compared with 1 out of 27, $P < 0.05$, χ^2 test).

Folic acid, vitamin C, vitamin B₂ and vitamin B₆ results

The incidence of low serum folic acid in Group 1 was 12% with the dementia group having an incidence of 10%. There was no significant difference between the dementia group and the functionally ill group. In Group 2 the incidence was 8.5%, all the patients being in the dementia group.

The incidence of vitamin C deficiency was 24% in Group 1 and 13% in Group 2. In both groups the functionally ill had a higher incidence of vitamin C deficiency. With respect to vitamins B₂ and B₆, deficiencies were found only in Group 1 but there was no significant difference between Groups 1a and 1b.

Discussion

This study has shown that there are significant differences in nutritional status between new admissions to a psychogeriatric unit and those already in long-term care. Also, demented patients within both groups tend to have significantly more abnormalities, with those in long-term care having better status than those on admission.

Significantly more patients on admission had abnormally low values for vitamins and essential minerals with 57% of those diagnosed as functionally ill and 79% of those suffering from dementia showing abnormalities. For those in long-term care the incidence was 33% and 62% respectively but the mean number of abnormalities per patient was much less being 0.67 for the functionally ill in long-term care compared with 1.28 for those on admission and 1.08 for those with dementia in long-term care compared with 1.8 for those on admission.

This finding that patients with dementia are more at risk of nutritional deficiencies is in agreement with the work of Sneath *et al* (1973) who found that demented elderly patients were more at risk of folic

acid deficiency than elderly patients suffering from other illnesses. The incidence of 8.5% with folic acid deficiency, in long-term patients is much lower than the 25% incidence found by Vir & Love (1979) in institutionalised elderly patients. These lower values perhaps indicate that the diet of patients living in the East End of Glasgow is better nutritionally than in some comparable areas. Patients in long-term care would, however, appear to improve their folic acid status on hospitalisation.

New admissions were more at risk of having lower vitamin B₁ and B₆ status and serum vitamin A levels, and also more at risk of having abnormally low vitamin B₂ status than long-term patients. No relationship was found between those diagnosed as functionally ill and their B₂ and B₆ status, as suggested by Carney *et al* (1982). New admissions with dementia however, had significantly lower values for serum zinc and vitamin B₁₂ and were more at risk of having abnormally low serum iron than new admissions with functional illnesses.

A lower serum zinc in dementia patients has been noted by other authors and is reviewed by Tiggelen (1983).

In this study many patients were found, on admission, to be deficient in vitamin B₂, serum vitamin C, zinc and iron. The incidences were 12%, 24%, 28% and 22% respectively. The corresponding values for those in long-term care were 0%, 13%, 21% and 16%. With respect to the vitamin C levels, these figures are again lower than those quoted by other authors; 57% in senile dementia patients (Shaw *et al*, 1984), 29.2% in institutionalised elderly patients (Vir & Love 1979) and 34% of all new admissions to a psychogeriatric unit (Hancock *et al*, 1985).

Conclusions

This study has shown that psychogeriatric patients, especially those with senile dementia are at risk of nutritional deficiencies. In view of the evidence

linking such deficiencies with mental disorders these may well contribute to the psychological morbidity of this group.

Acknowledgements

We are grateful to the Blood Transfusion Laboratory, Glasgow Royal Infirmary for performance of folate and vitamin B₁₂ analyses, and to the staff of the Metabolic Laboratory, Department of Biochemistry. Thanks are also due to Kåbivitrut, Stockholm, Sweden for financial support.

(Accepted 19 December 1985)

A Survey of Practising Psychiatrists' Views on Treatment of the Depressions

M. S. ARMSTRONG and G. ANDREWS

The views of practising psychiatrists on treatment of the depressions were investigated as part of a Quality Assurance Project. A one in six random sample of all Australian psychiatrists was mailed a questionnaire. This asked for treatment recommendations for each of five case descriptions of patients with depression. Respondents were asked to code their treatment plans from a glossary listing possible treatments for depression: 85% of the sample responded. Tricyclic antidepressants were the treatment of choice for two cases of endogenous depression, electroconvulsive therapy (ECT) being recommended when psychotic features were present or when drug therapy had failed. Psychotherapies were the treatment of choice for cases with neurotic features, drugs being recommended when improvement with psychotherapy did not occur.

The Australian Quality Assurance Project (QAP, 1982b) has prepared treatment outlines for the commoner psychiatric conditions: agoraphobia (QAP, 1982a), the depressions (QAP, 1983), the schizophrenias (QAP, 1984), and anxiety states, obsessional compulsive disorder and somatoform disorder (QAP, 1985a,b,c).

Three sources of information were used: the results of controlled trials, reports from a sample of practising psychiatrists, and the opinions of psychiatrists believed to be expert in the treatment of the disorder under study.

Information from the literature is limited as, almost without exception, single treatments only are explored, while the opinions of experts may be limited by personal bias. Information about treatment practices of experienced psychiatrists is potentially of value for their management plans make it clear that seldom are single treatments used in isolation, while the sampling procedure should limit the effect of personal bias.

This paper is a report of a sample of practising psychiatrists' views about the treatment of five persons suffering from various depressive syndromes.

Method

The problems confronting those who would survey the treatment methods of practising clinicians have been discussed by Hall *et al* (1982). These authors used a questionnaire to investigate the views of practising psychiatrists on the treatment of agoraphobia. The questionnaire employed two strategies. The first required respondents to describe treatment plans for each of three

agoraphobic patients described in vignette. The three cases varied in treatment history and personality characteristics. The second strategy had practitioners select preferred treatments for 'agoraphobia' from a comprehensive list, and note indications and contraindications for each of the recommended treatments.

Not surprisingly, the strategies employed by Hall and his colleagues were found to produce different response biases. Hall concluded that a combination of the two approaches, including a glossary of treatment options, would have ensured more "... agreement on terms between those who ask and those who answer the questions: an advantage that would probably offset any bias produced in the responses." In the present study it was decided to persist with the questionnaire method of survey, but to include the glossary and certain other modifications that appeared desirable from the experience of Hall and his colleagues.

The questionnaire

The questionnaire included five case descriptions of patients referred to a psychiatrist by general practitioners for the treatment of depression. Attached to the questionnaire was a glossary of 54 possible treatments, defined where necessary. Inclusion of the glossary of treatments meant that respondents could code their own answers to the questionnaire by using the numbers identifying treatments (for example: '01' specified the tricyclic antidepressants; '34' specified 'psychotherapy, supportive/counselling'). The five case descriptions were based on patients for whom long-term follow-up data were available. Diagnoses were given, using the ICD-9 and DSM-III classifications, and were to be regarded as correct by respondents. The histories were chosen to illustrate a broad spectrum of depressive illnesses. For mnemonic convenience the five cases have been identified in the text as follows: Case 1—ED (endogenous depression); Case 2—PD (psychotic depression); Case 3—ND (neurotic

depression); Case 4—ED/ND; Case 5—Adj Rn (adjustment reaction).

Following each case history were rows of coding boxes in which the clinician could specify his treatment plan using the code numbers from the glossary of treatments. Treatment components introduced at the same time were able to be distinguished from those introduced later in the therapy sequence. Space was provided following coding boxes for each respondent to describe details of treatments identified by particular code numbers, for example: [01] "Amitriptyline 75 mg nocte. I would vary this dose depending on patient's tolerance, but with probable eventual aim of 150 mg nocte." [34] "Supportive psychotherapy to aid coping with practical difficulties: side-effects of medication, family concerns etc. Initially twice per week plus telephone contact and/or extra consultations as necessary."

Seven questions were asked about each case history. They were the location of treatment, therapy plan, critical component of that plan, extra historical information required, duration of therapy before discharge to general practitioner if therapy successful, duration of therapy before choosing an alternative treatment plan if therapy unsuccessful, alternative treatment plan. Data will be presented as percentage of respondents making particular recommendations, and for the treatment duration items as medians and semi-interquartile ranges.

The sample

The 1154 psychiatrists practising in Australia in January 1981 were identified from the list of College members, from the Department of Health list of psychiatrists in private practice, and from a commercial mailing list verified using the Medical Directory of Australia (1980). A one in six random sample stratified by state was chosen and approached to participate in the surveys associated with this project. Following exclusion of refusers and persons overseas, 185 practitioners were approached to complete a structured questionnaire on the treatment of the depressive states: 157 codeable responses were received (85% response rate).

Data coding and analysis

Only those coding boxes in which an average of more than 1% of the sample had made responses were analysed. For each case, individual therapies were summed across respondents irrespective of in which box the therapy had originally been coded, to give the total number of respondents employing a particular therapy (say, tricyclic antidepressants). Therapies employed in a particular case are thus presented for all respondents.

Results

Sample characteristics

The present sample is virtually identical with that surveyed by Hall *et al* (1982). Since these authors have presented demographic and other data in some detail, this information is not duplicated here.

Questionnaire results:

Case vignettes and treatment recommendations

Case 1: Vignette

Mrs A is a 47-year-old deserted wife with a 19-year-old son and a 15-year-old daughter. Her husband left her 7 years ago and since then she has coped well bringing up her children. She was described by her brother as 'normally bright and lively . . . gentle, home loving, quite a capable person'.

Over the last year she has become increasingly depressed and agitated. She has lost interest in her home, feels that her actions are slowed, and has great difficulty in doing any housework. She has started to "worry about everything . . . the children . . . their future . . . the financial part of it . . . about accidents, about death". She feels that she is a failure, that she is lazy and unworthy, and suspects that in some way she has brought the illness upon herself. She says that things feel changed, unreal ". . . as if I am in another world". She is anorexic, has a dry mouth and has lost 1.5 stone in weight over the last few months. She sleeps very patchily, wakes at 3 a.m. and gets up and paces the floor. Her depression is at its most severe during these early hours.

Mrs A's mother suffers from recurrent endogenous depressions and has had numerous admissions to psychiatric units; on one occasion she cut her throat in an attempt at suicide. Mrs A's oldest brother (she is the youngest of four sibs) died some years ago in a car accident. He is said to have been "heading for a nervous breakdown . . . depressed . . . talking about driving into another car . . ."

Mrs A was referred to you for treatment by her general practitioner. She had been taken to see him by her brother whom she had telephoned after taking a small overdose of sleeping tablets. She has not previously been referred for psychiatric treatment nor has she experienced any previous depressive episodes. At interview she was preoccupied with her depression but realised that she was ill and was grateful at the prospect of effective treatment.

DIAGNOSTIC CLASSIFICATION:

ICD-9 [296.1] Manic-depressive psychosis, depressed type.

DSM-III [296.23] Major depression, single episode, with melancholia.

Recommendations

Seventy-two per cent of respondents felt this woman should be treated as a voluntary inpatient, a further 1.3% noting that her stay in hospital should be involuntary if necessary; 21% considered that she should be treated as an outpatient.

Almost 99% recommended antidepressant drugs (tricyclics 92.4%, tetracyclics 4.5% and MAOIs 1.9%) which smaller numbers combined with other physical treatment methods including electroconvulsive therapy (ECT) (17%), neuroleptics (14%), and benzodiazepines as anxiolytics (11%) or hypnotics (19%). Essentially all respondents recommended some form of psychotherapy: individual, group, or family, as a concurrent or later element of therapy.

Therapy for this patient was advanced with a great deal of confidence, only 7.6% of the sample failing to advocate a particular therapeutic element as critical. More than eight out of ten saw antidepressants as "most critical" (tricyclics 79%, tetracyclics 3.2%); the remainder mentioned ECT 4.5%, some form of psychotherapy (total for glossary codes 32-35) 2.4%, referral to inpatient unit for treatment 1.3%, lithium 0.6% and family/marital therapy 0.6%.

Therapy occupied a median of 12.2 h (semi-interquartile range [SIQR] 5.3 h) of the psychiatrists' time. If therapy proved unsuccessful an alternative plan of management was considered after 3.5 weeks (SIQR 0.9). At this stage 69% said that they would introduce a new treatment plan, 21% continued on an essentially similar plan, 5% said that they would refer for a second opinion and 3% that they would refer the patient on for further management.

Of those who proposed a new treatment plan, all included ECT; the only other marked differences from originally proposed patterns of treatment were increased proportions recommending MAOIs (20%) and tetracyclics (11%).

Case 2: Vignette

Mr B is a 32-year-old immigrant of British stock. The sixth child in a working class family of ten children, he left school at 14 to work in a textile factory. As a child, he said, he had been shy and very close to his parents, both of whom are alive and well. He continued working in the same factory until at the age of 19 he decided to emigrate to Australia "because of the greater opportunities".

On arrival in Australia he lived in a hostel for the first 12 months, working as a surgical dresser in a large hospital. Several months after his arrival he developed a serious depressive illness which was successfully treated with ECT. A similar illness recurred 2 years later but was treated, he thinks, with "pills and injections". He remembers little of either illness "... looking back they just seem like bad dreams".

He subsequently enrolled in and completed nursing training and has been working as a registered general nurse, a job which he enjoys, for several years. He remains a quiet self-effacing man given to periods of self-doubt. His life has improved over the past 5 years since the advent of a steady girlfriend with whom he now lives. "Her confidence and energy are important to me." They plan to marry and "start raising a family" in about a year's time.

Five weeks ago, without apparent cause, Mr B again started to become depressed. He lost interest in his work, in his girlfriend, and in life generally. He had no appetite and had lost more than a stone in the last month. He was waking after only 2 hours' sleep. He became convinced that his body was "an empty shell ... that nothing exists ... the world and all the people in it are doomed".

Mr B was referred for treatment by his general practitioner whom he had seen at his girlfriend's insistence. On initial interview he was withdrawn, retarded, and preoccupied with his delusions.

DIAGNOSTIC CLASSIFICATION

- | | | |
|---------|----------|--|
| ICD-9 | [296.1] | Manic-depressive psychosis, depressed type. |
| DSM-III | [296.34] | Major depression, recurrent, with psychotic features (mood congruent delusions). |

Recommendations

Eighty-eight per cent of respondents recommended that this man be treated as an inpatient (included in the 88% were 16% who felt that he should be held involuntarily, half of this latter group noting that involuntary status should be invoked only if necessary). Interestingly 9.6% suggested that they would manage this man as an outpatient; a further 1.3% suggested management as a day patient.

Physical methods of treatment predominated, nearly nine out of ten practitioners prescribing antidepressant medication (tricyclics 87.3%, tetracyclics 1.3%). These drugs were combined with ECT by slightly more than half (53.5%), and/or neuroleptics (phenothiazines 27.4%, butyrophenones 2.5%). Benzodiazepines were included as hypnotics by 17.8% and as anxiolytics by 5.1%. Lithium prophylaxis was initiated by 26.8%. As in Case 1, the majority of practitioners saw some form of psychotherapy as an important element of therapy, one in three considering that therapy for significant others or marital therapy should be included.

Respondents advanced treatment plans for this man with as much confidence as in Case 1, only 7.6% of the sample failing to label a particular element of therapy as 'critical'. Electroconvulsive therapy and tricyclics were proposed as critical elements approximately equally as often (42.7% and 41.4% respectively). Other treatments considered 'critical' were phenothiazines 2.5%, supportive psychotherapy 2.5%, referral for inpatient treatment 1.3%, brief analytically oriented psychotherapy 0.6%, family/marital therapy 0.6% and a period in hospital without treatment 0.6%.

Therapy occupied a median of 15.5 h (SIQR 9.7) of the psychiatrists' time. If unsuccessful the therapy was persisted with for a median of 3.5 weeks (SIQR 1.0) before a change in management was considered. At this stage 62% introduced a new treatment plan, 24% persisted with an essentially similar therapy, 11% asked for a second opinion and 2% referred the patient on for further treatment.

Of those psychiatrists who introduced a new treatment plan the most striking differences in therapy were the proportion now recommending ECT (93%), tetracyclics (12%), MAOIs (13%), phenothiazines (35%) and lithium (35%). There were reductions in the proportion including any form of psychotherapy as part of their new treatment plan.

Case 3: Vignette

Mrs C, an attractive 25-year-old, was the younger child and only daughter of a respected and "highly moralistic" father who was "active in many church organisations". Her mother was "soft, sensitive, too emotional".

At school she was an above average student, popular, but more so with boys than with girls. She enjoyed dancing and wanted to take it up as a career. Becoming pregnant at 15 she decided to conceal the pregnancy from her parents and left home, subsequently marrying the father. When this young man deserted her after the birth of a second child she took an overdose of nitrazepam. Following counselling, and with the support of her parents she began to achieve some acceptance of her situation.

Four years later she was working as a dancing teacher, supporting her two children, and living in a home unit which

she was paying off with her parents' help. She had a boyfriend she had been seeing for 1 year and hoped to marry. During the 4 years she had protracted periods of feeling "down in the dumps", separated by short periods of no more than a few months when she would feel like her "usual self". During the depressive times she felt tired and lacking in energy, but continued to work. Her dancing would give her less pleasure; and she would have occasional spells of weeping.

Three weeks before referral Mrs C again became depressed. She had been irritable with her children and was pessimistic about the future. At initial interview she was keen for help and the therapist was able to establish a good rapport. She said that she was depressed because her responsibilities were "... just too great". She compared herself unfavourably with married schoolfriends and said that she had "... always felt inadequate as a mother" ... "that things always go wrong for me no matter how hard I try". She had been referred for treatment by her general practitioner to whom she had gone after an episode of "uncontrollable crying" at work.

DIAGNOSTIC CLASSIFICATION:

ICD-9 [300.4] Neurotic depression.

DSM-III [300.40] Dysthymic disorder.

Recommendations

An overwhelming majority suggested that this lady be managed as an outpatient (96.8%); the remainder recommended voluntary inpatient (1.3%), day patient (0.6%) or were uncertain (1.3%).

The most commonly recommended therapies were the psychotherapies: psychoanalytically oriented (31.2%), brief psychoanalytically oriented (33.1%) and supportive (35.7%). "Other" psychotherapies were suggested by 10.8%, behaviour therapy by 7% and cognitive therapy by 6.4%. Counselling for significant others or family/marital therapy were advised by 18.4%. Antidepressants were included as an element of therapy by one in three, tricyclic antidepressants being favoured twice as often as MAOIs. Benzodiazepines were included as anxiolytics by 10.8% and as hypnotics by 3.8%.

In sharp contrast to the first two cases, less than two-thirds of the respondents were willing to label any particular element of therapy as 'critical' (34.4%, no recommendation). Curiously those psychiatrists recommending more intensive psychotherapies were less confident about labelling such therapies as 'critical' than those recommending supportive therapy. Those proposing psychoanalytically oriented therapy as 'critical' (12.1%) represented little more than one in three of those employing that therapy, brief psychoanalytically oriented therapy (15.3%) about half of those using that therapy, while supportive therapy (22.3%) approached two-thirds of those advocating its use. Other therapeutic methods labelled as 'critical' included cognitive therapy (5.1%), 'other' forms of psychotherapy (3.8%), family/marital therapy (1.3%), MAOIs (1.9%), tricyclics (1.3%), and each of the following 0.6%: psychoanalysis, hypnotherapy, 'other' group therapy and lithium.

A median of 29.6 h (SIQR 16.9) of the psychiatrists' time was anticipated as necessary for successful outcome. When

the initial treatment plan was unsuccessful, an alternative plan of management was considered after a median of 9.6 weeks (SIQR 3.4). At this stage 61% introduced new treatment, 15% continued essentially similar treatment, 12% sought a second opinion and 10% referred the patient on for further treatment.

Of those introducing new treatment, the most notable change was in the proportion who now advocated antidepressants: tricyclics (54%), MAOIs (25%) and tetracyclics (4%); other therapies more often proposed in the revised treatment plan included supportive psychotherapy (42%), cognitive therapy (10%), psychodynamically oriented group therapy (6%), 'other' group therapy (5%), hypnotherapy (6%) and psychoanalysis (3%).

Case 4: Vignette

Mr D, a 65-year-old solicitor, has been living alone in an inner city unit for the last 4 months.

His wife of 25 years died from asthma 9 years ago. After what seems to have been a natural mourning process, he continued his customary business, social and sporting life. A keen yachtsman, he is a popular but reserved member of his local club. Six months ago he began living with a woman he had been courting for 3 years with a view to marriage. She went to live with him in his original home, but this development was not a success. He became very anxious and the relationship broke up in a matter of weeks. In rather a panic Mr D sold this home and purchased his present unit. He says he made the decision to sell the family home because, "... she wanted to change everything that I was comfortable with ... it just wasn't right, and I'm not happy in the house any more."

Until this time Mr D feels that he led a "charmed life", with a "good marriage, loving and diligent children and enough time and money to enjoy the good things of life." He was the only child of a doting mother and a solicitor father who were very close. His mother died from heart failure when Mr D was 32 years old; his father died of pneumonia the next year. Mr D had successfully risen to full partnership in the family law firm.

In the last months he has lost interest in yachting and in his work. He has been avoiding living in his new unit, feeling terrified of being alone at night and complains of disturbing dreams and waking 1-2 hours earlier than his normal time. It seems that he can sleep better if staying with relatives or friends. In fact his daughter says that when staying with them, provided there are no outside demands, he is nearly his old self. He now laments his haste in selling the family home; he feels quite unable to make any decisions about his future, let alone act on them. He has begun to miss his wife again and says "it's as if she has just died", and "I really don't see any point in struggling on." He complains of persistent feelings of depression, of constant fatigue unrelated to effort, and feels he is only eating from habit.

He was referred to his GP by his married children with whom he was normally in frequent contact. They had become concerned at his withdrawn and pessimistic behaviour.

At interview he quickly developed rapport and made it clear that he felt that the psychiatrist could be of great help. He described himself as a "yacht without a rudder ... needing

direction and guidance." He appeared depressed, mildly anxious, talked freely and showed no psychotic phenomena or suicidal ideation.

DIAGNOSTIC CLASSIFICATION:

ICD-9 ? [300.4] Neurotic depression.

DSM-III ? [296.22] Major depression without melancholia.

Recommendations

Respondents advised treatment locations as follows: outpatient (85.4%), inpatient (8.3%), day patient and night patient each 1.9%, and uncertain 2.5%.

In the treatment recommendations for this clinically complex case psychotherapies and pharmacotherapies were given roughly equal weight. The most frequently proposed form of psychotherapy was supportive (59.2%); other psychotherapies included brief psychoanalytically oriented (29.9%), "other" (8.3%) and psychoanalytically oriented psychotherapy (5.7%). Counselling for significant others or family/marital therapy was recommended by 11.5%. Antidepressants were exhibited by 56.6% (tricyclics 47.1%, tetracyclics 5.7% and MAOIs 3.8%), and a benzodiazepine was included as an anxiolytic (22.9%) or hypnotic (17.8%).

Nonetheless psychotherapies were considered 'critical' very much more frequently than were pharmacotherapies. Psychotherapies proposed as critical included supportive (36.9%), brief psychoanalytically oriented (15.9%), 'other' (4.5%), psychoanalytically oriented (3.8%). Antidepressants were considered critical by 12.7% (tricyclics 10.2%, MAOIs 1.9%, tetracyclics 0.6%). The proportion of the sample unwilling to label any treatment as critical was 23.6%.

Therapy was expected to consume a median of 15.2 h (SIQR 4.9) of the psychiatrists' time, while unsuccessful therapy was persisted with for a median of 5.6 weeks (SIQR 2.2). New treatment was introduced by 61%, similar therapy was continued by 21%, a second opinion was sought by 12% and 5% referred the patient on for further treatment.

Of those proposing new treatment, the major change was in the proportion now advocating antidepressants, alone or in combination (tricyclics 79%, MAOIs 28%, tetracyclics 9%).

Case 5: Vignette

Miss E is a 20-year-old nurse in the last year of training. She was the oldest in a family of three and described her parents as "strict, religious and kind". She attended a convent school and was intending to matriculate when increasing arguments with her father made her decide to leave home and commence nursing at a Catholic hospital.

She enjoyed nursing and was well regarded by her superiors. She lived in the nurses' home until a year ago when she was persuaded to share a flat with friends. She enjoys this arrangement, since she has "far more freedom" than at home or in the nurses' home. She has had a steady boyfriend for the past three years. During the first two years the relationship was sexually conservative as befitted their religious background. Since moving into the flat it has become overtly sexual. She now feels that this change was unwise and that her boyfriend is losing interest in her.

A month ago she learnt that because of illness in the earlier part of her nursing career she will not be eligible to complete her finals with the rest of her class.

In the past month she has been withdrawn, unable to study at nights, sleeping poorly and not wanting to see anybody. She says, "I only find satisfaction in nursing my patients" and that nothing else seems to matter. She has become depressed, is often discovered weeping quietly and while she admits that she may be "blowing things out of all proportion", she is unable to behave differently.

Her flatmates took her to see her local GP after she had spent the weekend crying in her room. At interview she attributed her depression to her "unwise" sexual behaviour and to her pending separation from her classmates. She offered information readily and concluded by saying, "I'm usually so sensible, I don't understand why I can't cope!"

DIAGNOSTIC CLASSIFICATION:

ICD-9 [309.0] Adjustment Reaction, Brief Depression

DSM-III [309.00] Adjustment Disorder with Depressed Mood.

Recommendations

The majority of the practice sample (86.6%) recommended that this young woman be treated as an outpatient; of the remainder 8.9% thought that she should be treated as an inpatient, 1.3% as a day patient and 3.2% were uncertain.

Nearly all respondents recommended some form of psychotherapy, either as a concurrent or later element of therapy. These psychotherapies included brief psychoanalytically oriented (47.8%), supportive (47.1%), 'other' (7%) and psychoanalytically oriented (6.4%); some form of group therapy was proposed by 3.8%, and cognitive or behavioural therapy by 3.2%. Counselling for significant others or family/marital therapy was recommended by 8.3%. Pharmacotherapeutic treatments were advised sparingly, 19.1% suggesting tricyclics and 3.2% MAOIs, either alone or in combination with a benzodiazepine as an anxiolytic (17.2%) or hypnotic (15.3%).

The practice sample were least certain in this case about which element of treatment was most likely to be 'critical', 38.9% being unwilling to note as such any treatment. Of those who did propose 'critical' treatments, supportive psychotherapy (26.8%) was favoured slightly more often than brief psychoanalytically oriented therapy.

It was anticipated that a median of 14.6 h would be devoted to therapy; unsuccessful treatment was persisted with for a median of 5.8 weeks (SIQR 3.2). New treatment was introduced at this stage by 28%; 12% each referred Miss E for second opinion or further treatment.

Amongst those psychiatrists introducing new treatment, analytically oriented psychotherapies, individual (brief analytically oriented psychotherapy 60%, analytically oriented psychotherapy 24%) or group (psychodynamically oriented 10%), and/or antidepressants (tricyclics 50%, MAOIs 14%) were most often considered important.

General overview of questionnaire results

In this section a general overview of results, with an emphasis on cross-case comparisons, is presented for each

of the questions. For mnemonic convenience the five cases have been identified in the text as follows: Case 1—ED (endogenous depression); Case 2—PD (psychotic depression); Case 3—ND (neurotic depression); Case 4—ED/ND; Case 5—AdjRn (adjustment reaction).

Location of treatment

The most striking differences in recommendations for location of treatment were between those for patients with clearly major depressive illnesses (ED and PD) for whom a majority of psychiatrists favoured inpatient treatment, and those patients with other depressive illnesses, for whom a majority of psychiatrists preferred outpatient treatment. Involuntary admission emerged as a significant issue only in Case 2 (PD).

Therapy plan

Therapies employed by two or more percent of respondents (in at least one case) are given for all five cases in Table I; the results are presented as the percentage of all respondents who advised a particular therapy. Virtually all psychiatrists said they would use more than one treatment, ranging from 3.0 treatments for Case 1 to 1.8 for Case 5.

Critical treatment

Practitioners were asked which element of their treatment plan they considered 'most critical'. If, for example, a tricyclic antidepressant and 12 sessions of psychotherapy

had both been advised, which, if either, was considered more important?

A great variety of treatments were labelled as 'critical'. In the interests of clarity only those labelled by 5% or more have been listed. Where respondents were not prepared to label any treatment as 'critical', data have been recorded as 'no recommendation'.

'Critical treatments' for each case follow; percentages have been rounded to integers.

Case 1 (ED): tricyclic antidepressants 79%; ECT 5%; no recommendation 8%.

Case 2 (PD): tricyclic antidepressants 41%; ECT 43%; no recommendation 8%.

Case 3 (ND): psychoanalytically oriented psychotherapy 12%; brief psychotherapy 15%; supportive psychotherapy 22%; cognitive therapy 5%; no recommendation 34%.

Case 4 (ED/ND): tricyclic antidepressants 10%; brief psychotherapy 16%; supportive psychotherapy 37%; 'other' psychotherapy 5%; no recommendation 24%.

Case 5 (AdjRn): brief psychotherapy 24%; supportive psychotherapy 27%; no recommendation 39%.

Hours of treatment

This question enquired how many hours of the psychiatrist's time, assuming that the patient made progress, would be required from initial assessment to return of the patient to his or her general practitioner's care.

TABLE I
Percentage of respondents ($n = 157$) recommending a particular treatment as initial therapy, and, in parentheses, percentage of those advising a new treatment if first management plan did not result in improvement

Treatment	Case 1 (ED)	Case 2 (PD)	Case 3 (ND)	Case 4 (ED/ND)	Case 5 (AdjRn)
Tricyclic	93 (79)	87 (82)	20 (54)	47 (79)	19 (50)
Tetracyclic	5 (11)	1 (12)	1 (4)	6 (9)	0 (1)
MAOI	2 (20)	0 (13)	10 (25)	4 (28)	3 (14)
Phenothiazine	14 (10)	27 (35)	3 (2)	3 (3)	1 (3)
Butyrophenone	0 (0)	3 (3)	0 (0)	0 (0)	1 (1)
Benzodiazepine (as anxiolytic)	11 (7)	5 (5)	11 (15)	23 (14)	17 (14)
Benzodiazepine (as sedative)	19 (14)	18 (9)	4 (4)	18 (12)	15 (17)
Lithium	6 (6)	27 (35)	2 (5)	1 (0)	0 (0)
Vitamin	4 (0)	2 (2)	1 (0)	2 (0)	0 (0)
ECT	17 (100)	54 (93)	0 (0)	1 (0)	0 (0)
Analytically oriented psychotherapy	3 (1)	5 (1)	31 (33)	6 (8)	6 (24)
Brief analytically oriented psychotherapy	5 (2)	10 (3)	33 (20)	30 (21)	48 (60)
Psychotherapy, supportive/counselling	83 (70)	73 (53)	36 (42)	59 (59)	47 (49)
Psychotherapy, other	7 (6)	6 (3)	11 (7)	8 (4)	7 (8)
Counselling for others	10 (5)	20 (5)	2 (1)	6 (2)	5 (5)
Behaviour therapy	1 (1)	2 (2)	7 (6)	1 (2)	1 (3)
Cognitive therapy	3 (3)	2 (2)	6 (10)	3 (4)	2 (5)
Hypnotherapy	0 (0)	1 (0)	3 (6)	3 (2)	1 (7)
Group psychodynamically oriented therapy	2 (1)	1 (1)	3 (6)	1 (1)	2 (10)
Group therapy, other	2 (0)	1 (1)	1 (5)	1 (2)	0 (5)
Supportive group	5 (5)	4 (2)	6 (3)	3 (3)	2 (1)
Family/marital therapy	11 (10)	13 (7)	8 (9)	5 (11)	4 (8)

TABLE II
Percentage of respondents (n = 157) taking a particular course of action for each of the five cases when the first treatment plan had not resulted in improvement

<i>Course of action</i>	<i>Case 1 (ED)</i>	<i>Case 2 (PD)</i>	<i>Case 3 (ND)</i>	<i>Case 4 (ED/ND)</i>	<i>Case 5 (AdjRn)</i>
Refer for second opinion	5	11	12	12	12
Referral on	3	2	10	5	12
Similar treatment	21	24	15	21	28
New treatment	69	62	61	61	46

A plot of the responses produced, for each of the five cases, a complex multi-modal distribution with marked positive skew, (that is, while most respondents suggested relatively low figures for hours of treatment, decreasing numbers of respondents suggested progressively higher figures.

With the exception of ND (Case 3) which had a median of 30 h, results were markedly consistent, the median psychiatrist recommending 12–15 h for the other four cases with half of the sample considering between 7 and 20 h would be required for treatment.

Weeks of treatment

This question asked how long the psychiatrist would persist with treatment if the patient failed to improve adequately, before considering an alternative plan of management. The data are reported as for hours of treatment above.

For ED and PD (Cases 1 and 2, respectively) in which physical treatments predominated, alternative treatment was considered after a median of 3.5 weeks; for ND and AdjRn (Cases 3 and 5), in which various forms of psychotherapy were the most frequently recommended treatments, a new treatment was considered after a median of 10 weeks (ND) and of 6 weeks (AdjRn). For ED/ND (Case 4), in which physical and psychotherapeutic methods were recommended about as frequently, psychiatrists were led to consider an alternative treatment at a median of 6 weeks.

A subsidiary question inquired about which of four courses of action would then be followed: referral for second opinion (psychiatrist or other specialist), referral on (to another psychiatrist/psychiatric institution), employ continuing course of essentially similar treatment, or introduce a new treatment. Results are presented in Table II as percentages of all respondents advising a particular course of action (figures are rounded to integers).

New therapy plan

The treatments advised for patients who had not improved are given in Table I (figures in brackets): the data are presented as percentages of those who proposed new methods of management, treated on a case-by-case basis. As presented, the figures thus allow cross-case comparisons of revised treatment plans for difficult cases.

Discussion

There are a number of important questions that must be considered in using a questionnaire method of survey to obtain the views of practising clinicians on optimal treatments for any group of illnesses.

In the first place, how representative are the questionnaire responses likely to be of the whole population of clinicians? Since the group for which results are analysed represents a large (14%) random sample of the whole population of psychiatrists practising in Australia, and the response rate (85%) was high, sampling error of questionnaire responses is likely to be insignificantly low, at least in the case of the major therapies described. It seems reasonable to infer that on the whole responses of this sample would differ little from those of the population.

A major assumption in using this method of survey to establish the treatment recommendations of practising clinicians, is that the recommendations reflect their actual practice. The most apparent danger inherent in the method is that the recommendations may reflect the ideal rather than the real, given the exigencies of everyday practice. In the case of the depressions, this possibility is arguably of little practical significance. For a number of reasons it seems probable that for the great majority of respondents, treatment recommendations are likely to have been based in considerable measure on personal experience. Depression is amongst the most common of reasons for referral to a psychiatrist; the patients described in the questionnaire are typical of those seen and treated in everyday practice. The therapeutic modalities proposed are likely to have been widely used: most respondents will have been trained in their use, the treatments are readily available and, except perhaps in the case of ECT, special facilities or referral to a specialist unit are not required.

A second question of major importance is just how optimal are the therapeutic practices of experienced clinicians? Two major issues bear on this question. The first is whether the practice of the clinicians reflects awareness of those treatments established by

the experimental literature as effective. This topic is discussed below in the light of the experimental data. The second issue, an assumption of very considerable importance, particularly in the case of those therapies or combinations of therapies that have little or no experimental validation, is that actual practice is based on a sensitive monitoring of what does and does not work. To what extent do clinicians alter their practice in the light of experience; to what extent do practice habits persist in spite of experience? The present paper does not, of course, provide data which bear on this question.

Therapy plan

In discussing the proposed treatment plans a number of important related issues can also be discussed. With what degree of confidence do clinicians suggest particular treatments for the various patients? How well does their confidence accord with the findings of the experimental literature?

In answering the first question, we feel that the questionnaire item, 'Critical treatment', provides pertinent information. The extent to which clinicians were prepared to label, or not label, particular treatments as 'critical' for successful therapy of a given condition, would seem to provide information about their degree of confidence in the efficacy of treatments in that condition. In those depressions presumed to have an important biological element in their determination, ED (Case 1) and PD (Case 2), treatments were proposed with a great deal of confidence, only 8% of respondents being unprepared to label any treatment as 'critical'. In sharp contrast, in depressions in which psychological factors are commonly thought to play an important role, ND (Case 3) and AdjRn (Case 5), respondents were a great deal less certain about what did and did not work, 34% being unwilling to label any treatment as critical in ND, and 39% in AdjRn. In ED/ND (Case 4), in which symptoms were somewhat equivocal, with suggestions of both biological and psychological elements, 24% of respondents would not indicate a critical treatment.

How well then do treatments advised or, more importantly, described as 'critical', accord with the findings of the experimental literature for a given condition?

In those depressions of principal biological determination physical methods of treatment predominated. In uncomplicated ED (Case 1) and in PD (Case 2), antidepressants and ECT were commonly prescribed and labelled as 'critical'. Antidepressants were advised by essentially all respondents in ED and by nearly nine out of ten in PD, and were described as

'critical' by 82% and 41%, respectively. Electroconvulsive therapy was advocated by 17% in ED and 54% in PD, being seen as 'critical' by 5% and 43%, respectively. Neuroleptics were prescribed by 14% in ED and 30% in PD, but were seen as 'critical' only in PD (by 2.5%); benzodiazepines were prescribed by almost 30% and 23%, respectively. Although some form of psychotherapy and/or family/marital therapy was advised by nearly all respondents in both cases, it was rarely seen as 'critical'. There is on the whole a high degree of concordance between such treatment prescriptions and the treatment literature of endogenous and psychotic depressions: ECT and antidepressants, with the probable exception of the MAOIs, were found effective in these disorders in our review of the literature (Quality Assurance Project, 1983).

In the non-endogenous depressions, in which psychological determinants are presumed to be of major importance, the psychotherapies were most commonly advised, combined with antidepressants by between one in two and one in five respondents. In ND (Case 3), psychoanalytically oriented, brief psychoanalytically oriented and supportive psychotherapies were each suggested by about one-third, and were seen as 'critical' by 12%, 15% and 22%, respectively. Brief psychotherapy and supportive psychotherapy were commonly advised in AdjRn (Case 5) (48% and 47%) and in ED/ND (Case 4) (30% and 59%), being considered 'critical' in AdjRn by 24% and 27%, and in ED/ND by 16% and 37%. Cognitive or behavioural therapy was suggested by 13% in ND and seen as 'critical' (cognitive therapy) by 5%. While advocated in all three cases, antidepressants were considered 'critical' only in ED/ND, by 10% (although prescribed in this case by more than 50%). Tricyclic antidepressants were prescribed by 20% in ND and AdjRn, and MAOIs by 10% in ND. The only other therapy suggested with any frequency was a benzodiazepine, advised by 15% in ND, by 32% in AdjRn and by 41% in ED/ND. In these non-endogenous depressions the degree of concordance between the literature and treatments recommended is not as high. Antidepressants are prescribed, and seen as 'critical' less frequently, and psychotherapies probably more frequently, than the literature would seem to support. It should be noted however, that with the exception of cognitive therapies, the literature is almost totally lacking in any controlled studies of verbal therapies in the depressions. Despite the apparent efficacy of cognitive therapy in neurotic depression (Quality Assurance Project, 1983), few clinicians advocated such therapy, presumably because the relatively recent development of such

therapies means that very few of the practice sample will have been trained in their use.

New therapy plan

In each of the depressive illnesses studied the major change in pattern of therapy, for those clinicians who proposed a revised treatment plan should their initial plan prove unsuccessful, was towards physical methods of treatment. In the endogenous depressions alternative antidepressants were often advised and all or almost all now used ECT. In the non-endogenous depressions antidepressants were introduced, usually by rather more than one in two of those who suggested a new therapy plan. Referral for second opinion or further treatment was recommended by up to one in four of the clinicians. No controlled studies of new treatments in short-term therapy failure are known to the authors; under such conditions of therapy failure the practice sample clearly indicated that alternative treatments of established effectiveness should be employed.

Conclusion

The Quality Assurance Project (QAP, 1982b) has published treatment outlines for agoraphobia (QAP, 1982a), the depressions (QAP, 1983) and the schizophrenias (QAP, 1984); it is now proceeding to publish outlines for the remainder of the anxiety disorders and the somatoform disorders.

In the depressive disorders in particular three points have become evident in the course of the project. The research literature is a reasonable guide to practice even though drug studies are still typified by short follow-up periods, and non-physical therapies, with the exception of cognitive and/or behavioural studies, by their rarity. The responses of the practice sample show a high level of agreement, with no evidence that Australian psychiatry in the 1980s is beset by factional rivalries. Lastly, the Quality Assurance Project by using these

sources of information, the research literature and the opinions of a practice sample, and the advice of elected experts can develop a consensus about the practice of psychiatry ca 1982. Such an achievement should benefit practitioners, hearten trainee psychiatrists, and form a springboard from which research into therapeutics can proceed.

CLOPIXOL®

zuclopenthixol dihydrochloride/zuclopenthixol decanoate

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 30mg/day in divided doses.
Children Not recommended.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by antipsychotic drugs.
Contraindications Acute alcohol, barbiturate or other poisoning. Intolerance to other neuroleptics (relative). Use with caution in patients

with Parkinsonism, severe arteriosclerosis, senile confusion states, serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.
Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027, 0028, 0029. PA Nos 115/5/3, 4, 6.
CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia,

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Children Not recommended.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with

or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.
Package quantities & NHS price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. PL Nos 0458/0017, 0041. PA Nos 115/5/1, 5, 7.

A SCHIZOPHRENIC.

Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.

A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*
haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼ **Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. **Use in Pregnancy:** The safety of haloperidol in human pregnancy has not been established. **Precautions:** Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. **Side Effects:** In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50–100mg every 4 weeks; in moderate symptomatology 100–200mg every 4 weeks; in severe symptomatology 200–300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from **JANSSEN** Pharmaceutical Limited, Grove, Wantage, Oxon OX12 0DQ.

**SOME PEOPLE'S IDEAS ABOUT
ST ANDREW'S ARE AS DATED AS
THIS ENGRAVING**

Established almost 150 years ago St Andrew's has always been in the forefront of psychiatric developments.

In the 1800's it was the first hospital to totally abolish physical restraint. As early as 1927 it opened a separate unit for short stay patients. In the 1980's it has pioneered the application of behavioural methods to the management of a range of disorders including severe brain damage.

The Effects of Weight Change on the Dexamethasone Suppression Test in Depressed and Anorexic Patients

I. SCHWEITZER, K. P. MAGUIRE, J. W. G. TILLER, A. H. GEE, L. C. HARRISON and B. M. DAVIES

Prior studies on weight change and hypothalamic-pituitary-adrenal (HPA) axis functioning are reviewed. Data on 58 depressed and eight anorexic patients is presented. No significant difference in the frequency of cortisol non-suppression in the dexamethasone suppression test (DST) was found between depressed patients with a history of weight loss and those without, nor between depressed patients who lost weight during their first week in hospital and those who did not. Mean weight loss of suppressors did not significantly differ from that of non-suppressors. Of 12 patients whose DST normalised during their stay in hospital, only four gained weight. Five anorexics who were non-suppressors were < 70% of their ideal body weight (IBW), while three suppressor anorexics were $\geq 70\%$ IBW. These results indicate that mild to moderate weight change is not a significant influence on DST response in depression.

Studies of hypothalamic-pituitary-adrenal (HPA) axis functioning and its relationship to depression commenced in the 1960s (Sacher *et al*, 1970, Carroll, 1971). Early work concentrated firstly on urinary metabolites of cortisol and then on plasma cortisol levels. During the 1970s, dynamic studies of central HPA axis regulation became possible. In general, these studies have concluded that some depressed patients have altered HPA axis regulatory mechanisms similar to those found in Cushing's disease. These abnormalities include excessive cortisol secretion with increased nocturnal release, impaired responsiveness to lysine vasopressin and to hypoglycaemia and non-suppression of plasma cortisol following the administration of dexamethasone (Carroll *et al*, 1976). Due to its ease of application, the dexamethasone suppression test (DST) has been the most widely investigated test of these regulatory abnormalities and approximately 50% of depressed patients have been found to be non-suppressors of cortisol (Hirschfeld *et al*, 1983). However, the cause and mechanism of these HPA axis abnormalities remains unclear.

The relationship between weight change and alterations in HPA axis functioning has also been recognised. As weight loss is a common feature, it has been suggested that this factor alone might be responsible for non-suppression of cortisol in the DST (Edelstein *et al*, 1983). The purpose of this project was to examine this question in a systematic, prospective manner and to study several parameters

of weight change in depression in relation to the DST.

Background

The interaction of weight change and HPA axis functioning may be considered under five headings.

Fasting obese subjects

Galvao-Teles *et al* (1976), found significant increases in plasma unbound cortisol in a group of 13 fasting obese subjects. These changes were most marked at 2400 h, indicating a considerable diminution of the day-night variation of plasma unbound cortisol levels. Edelstein *et al*, (1983), studied 18 healthy, non-depressed overweight subjects before and after a protein-sparing fast. All patients received the DST and all suppressed cortisol normally before fasting. However, after 8-12 weeks of fasting, when subjects had lost an average of 14.3 kg, five (28%) of the subjects had become non-suppressors. There was no significant alteration in mood in these subjects. In both of these studies, patients were on stringent low calorie diets and lost substantial amounts of weight in a relatively brief period of time.

Fasting normal subjects

Berger *et al* (1984), studied 24 healthy volunteers who were placed on a 1000-1300 kilocalorie diet and who

lost an average of 1.5 kg/week. In nine (37.5%) of these subjects cortisol became non-suppressible to dexamethasone. Yerevanian *et al* (1984), studied 16 non-depressed volunteers and found that two (12.5%) converted from normal suppression to non-suppression after a period of strenuous dieting. Again, in both of these studies rigorous dieting was instituted resulting in sudden weight changes.

Starving subjects

Smith *et al* (1975), studied ten adult patients with protein-calorie malnutrition and found elevated levels of plasma cortisol, increased urinary excretion of cortisol, reduced metabolic clearance of cortisol, reduced plasma production rate of cortisol and non-suppression of cortisol following dexamethasone. Weight loss in all subjects was severe and several were in a state of inanition.

Anorexia nervosa patients

There are considerable data available (Weiner, 1977, Walsh, 1982) which indicate the frequent association of abnormalities of the HPA axis and anorexia nervosa. Anorexic patients have low urinary 17-OH corticosteroid levels, increased half-life of plasma cortisol, reduced metabolic clearance rate of cortisol, increased secretion rate of cortisol and elevated urinary free cortisol. Non-suppression of cortisol following dexamethasone has been found to occur in over 50% of anorexic patients (Gwirtsman & Gerner, 1981), approximating therefore the frequency in depression. These abnormalities of HPA axis functioning have been found mostly in the acute weight-loss stage of the illness when patients are less than 80% of their ideal body weight (IBW). They tend to normalise with response to treatment and gain in weight (Fichter *et al*, 1982), although this has been disputed (Gwirtsman & Gerner, 1981).

Depressed subjects with or without weight change

There have been a number of studies that have attempted to address specifically the question of the effect of weight change on the HPA axis in depressed patients. At present, results are conflicting. Carroll was the first to observe that 28 depressed subjects who had lost at least 3.2 kg in weight had significantly higher morning plasma cortisol levels than 12 subjects without such loss of weight (Carroll, 1971). Studies using the DST specifically have been of three types. One approach has been to examine the history for recorded data of recent weight change. Three studies of this type (Coppin *et al*, 1984;

Zimmerman *et al*, 1984; Yerevanian *et al*, 1984), found no relationship between a history of weight loss and DST response while two studies (Kline *et al*, 1983; Targum, 1983) both with small numbers of patients contradicted this finding. A sixth study (Feinberg & Carroll, 1984) found that weight loss was a significant variable but only when considered in isolation. When severity of the illness and the age of the patient were taken into account the history of weight loss was concluded to be an insignificant variable. These retrospective studies analysed case records, mostly by using the weight change item of the Hamilton depression rating scale or the Newcastle scale. These studies are therefore open to criticism because they are dependant on the reliability and details in documentation in the history and the care with which the weight change item had been assessed.

A second approach has been to measure weight change during the first week of a period in hospital and relate this to DST response. This is based on the assumption that such weight change will reflect and correlate with recent weight changes during the depressive episode and will therefore overcome the problem of historical inaccuracy. Two such studies (Feinberg & Carroll, 1984; Holsboer *et al*, 1984) both found no relationship between weight loss and DST response, while a third found weight loss to be a significant factor (Berger *et al*, 1983).

A third approach has been to monitor changes in DST response during the period in hospital, specifically the normalisation of the response. Only one (Targum, 1983) such study has been performed to date. This study found that three patients of ten whose DST failed to normalise during 6 weeks in hospital, gave a history of weight loss at admission.

Methods

Patients admitted to the Psychiatric Unit of The Royal Melbourne Hospital (RMH) were independently assessed by two psychiatrists. Those patients meeting DSM-III criteria for major depressive disorder (MDD) were included in the study. Carroll's exclusion criteria were applied (Carroll *et al*, 1981). All patients were assessed for severity of depression within the first few days of admission, using a Hamilton observer-rating scale and a Carroll self-rating scale. In addition to a careful history of recent weight change, all patients were weighed and their height was measured at admission. Wherever possible, family members were interviewed for further information concerning weight loss. During the first week (but not before the third day following admission) all patients received a standard DST with 1 mg of dexamethasone being administered at 2300 h and blood samples for serum cortisol being taken the same and following day at 1600 h. Plasma cortisol was analysed in the Department of Biochemistry (RMH) using the routine assay (Amerlex, Amersham, UK). Normal suppression was

defined as a post-dexamethasone serum cortisol concentration of less than 167 nmol/litre, a criterion established from a previous normal control study in the unit. All patients were re-assessed at weekly intervals during their period in hospital, with Hamilton and Carroll ratings, weighings and DSTs.

In addition, a group of anorexic patients have been studied. These patients were examined by two psychiatrists and all patients met DSM-III criteria for Anorexia Nervosa. Their assessments were similar to the depressed patients with weekly weighings, Hamilton and Carroll ratings, and standard DSTs.

As appropriate, χ^2 and *t*-tests were performed, for statistical analysis of the data. A $P > 0.05$ was used as the criterion for a non-significant (NS) result.

Results

History of recent weight loss

Of a total of 58 depressed patients studied, 29 were found to have had a recent history of significant weight loss (defined as more than 2 kg within the previous 2 months), while 29 gave no such history. Eleven of the 29 patients who had lost weight were non-suppressors of cortisol while nine of the 29 patients who had no history of weight loss were non-suppressors which represented no significant difference between the two groups (Table I). Furthermore, for the patients who had lost weight, the mean weight loss of the non-suppressors was 7 kg, while that of the suppressors was 5 kg. This difference was not significant. Also, both groups were only slightly below their mean ideal body weight (IBW), the mean for non-suppressors being 97% of their IBW and suppressors 95% of IBW.

$\chi^2 = 0.79$

NS

1. Defined as > 0.5 kg

2. Data unavailable on nine patients — early discharge or transfer or weighings missed.

The weight-loss vs the no-weight-loss groups were compared with regard to mean plasma cortisol levels obtained from the initial DST during the first week in hospital. The mean pre-dexamethasone plasma cortisol concentration, mean post-dexamethasone plasma cortisol concentration and mean change in plasma cortisol concentrations from pre- to post-dexamethasone levels were not significantly different in these two groups (see Table I). Also, there was no significant difference in the severity of depression at admission, as measured by the Hamilton depression rating scale, between the weight-loss and no-weight-loss groups (see Table I).

Weight loss as measured during the first week of stay in hospital

Of the 49 depressed patients on whom relevant data were available, 22 were found to have lost 0.5 kg or more during their first week of stay in hospital. Twenty-seven depressed patients lost no weight or gained weight during their first week. There was no significant difference in the frequency of non-suppression in the weight-loss group vs the no-weight-loss group (see Table II). Furthermore, there was no significant difference in the mean weight loss of the non-suppressor group versus the suppressor group, approximately 2 kg in each group.

Weight changes during the course of stay in hospital

Among the 58 patients studied, there were 17 non-suppressors of cortisol who completed at least 3 weeks of inpatient treatment. Of these 17 patients, 12 converted to normal suppression during their inpatient stay (mean stay 5 weeks), while five remained non-suppressors. Of the twelve patients who converted to normal suppression only four (33%) gained weight during their stay in hospital. Seven of the remaining patients did not significantly alter their weight during their hospital stays while one patient actually lost weight.

Anorexic patients

Of eight anorexia nervosa patients who were studied, five were non-suppressors at admission, while three were normal suppressors. All five non-suppressors were 70% or less of

their IBW at admission, while the three suppressors were over 70% of their IBW. There was no apparent correlation between non-suppression and clinical assessment of depression or Hamilton depression rating score. Of the five non-suppressors, four converted to normal suppression after several weeks of inpatient treatment and did so when their weights exceeded 70% of their IBW. The one anorexic patient who remained a non-suppressor failed to respond to treatment or to gain weight.

Discussion

Studies of non-depressed groups including obese, malnourished and anorexic patients as well as normal subjects all indicate that weight loss is frequently associated with abnormalities in several tests of HPA axis functioning, including the DST. These studies suggest that either severe loss of weight or sudden substantial losses of weight will result in changes in HPA axis functioning. However, none of these groups are strictly comparable to a depressed patient population. Weight loss in depression in current clinical populations, is usually mild and gradual and only rarely severe and/or rapid. Amongst our patient group, the average weight loss reported by those patients who had lost weight prior to admission was 5.8 kg over the previous 2–3 months. There was only one patient who had lost more than 12 kg in weight and only one patient who was less than 70% of her IBW. In marked contrast in our anorexic group only those patients who were 70% or less of their IBWs were non-suppressors of the DST. Also, these patients converted to normal suppression when their weight exceeded 70% of their IBW.

The majority of the studies that have addressed the issue of weight loss in depression and the DST, conclude that weight loss is not a significant variable, whilst two studies contradict this finding. Most of these studies can be criticised from the point of view of retrospectivity and some because of low numbers and lack of definition of degree of weight loss. Although history of weight loss must by necessity be retrospective, we have attempted to overcome the problems of previous work which has largely relied on the weight change item of questionnaires. Our patients were carefully and directly questioned with regard to recent weight loss and whenever possible family members were interviewed. Also in our study, we have included a prospective and objective approach by measuring weight change weekly during the patients stay in hospital.

Our results support those prior studies which conclude that mild to moderate weight change is not a significant influence on the DST response in depression; DST response was not significantly linked to reported history of weight loss or weight

loss as measured during the first week in hospital. In addition, there were 12 patients in whom the DST response normalised with treatment during their stay in hospital and in the majority of these patients (67%) there was no weight change during the corresponding period.

The cut-off point for normal suppression, a plasma cortisol of 167 nmol/litre, had been determined from a previous study of 100 normal volunteers who had undergone a standard DST—and Carroll's recommendation of 5% of a normal population as being non-suppressors was used to calculate this value. In fact, when our data was re-examined using our former cut-off point of a plasma cortisol of 138 nmol/litre, the DST status of only one patient changed, making no significant difference to our results. Also, when our data was analysed using patients' plasma cortisol concentrations rather than the suppressor vs non-suppressor category we again found history of weight loss was not a significant variable.

Although, acute and severe losses of weight may influence HPA axis functioning and consequently the DST response, this is not usually the case in depressive illness. We conclude that weight change need only be taken into account when interpreting the DST response in depressed patients, when weight loss is unusually severe or rapid.

Physical Illness A Risk Factor in Anorexia Nervosa

G. C. PATTON, K. WOOD and E. JOHNSON-SABINE

Reports have appeared in the literature suggesting an association between physical illness and the later development of anorexia nervosa. The histories of 326 patients with anorexia nervosa were examined for physical illness. A higher rate of severe physical illness was found in this group when compared with controls suggesting that it should be regarded as a risk factor for anorexia nervosa. No statistically significant differences were found when illness was examined by time in relation to onset of anorexia, system involved, or when subjects were stratified by age. Possible explanations for the observed association are discussed.

Ryle (1936) first suggested that there was an association between a history of severe physical illness and the later development of anorexia nervosa. From his series of 49 anorexic patients, he identified an older group for whom operations and illnesses appeared to play a leading part in the predisposition to the condition. Dally (1969) found that for 38 of his series of 140 patients with anorexia nervosa, the patients' mothers considered that there had been undue physical ill-health during the daughters' life before the onset of anorexia nervosa. The disorders included asthma, tuberculosis, congenital blindness, squint and deafness following otitis media. Recently reports of cases of specific conditions coexistent with anorexia nervosa have appeared, for example, Turner's syndrome (Pitts & Guze, 1963), (Kron *et al*, 1977), urogenital abnormalities (Halmi & Rigas, 1973) diabetes mellitus (Fairbairn & Steel, 1980; Szmukler & Russell, 1983) and neurofibromatosis (Fitzpatrick *et al*, 1983).

Apart from physical illness being a cause of vulnerability to anorexia nervosa, it has been suggested (Dally 1969; Beaumont *et al*, 1978) that physical illness may precipitate the onset of anorexia nervosa. Physical illness was hypothesised to induce a physiological anorexia which subsequently developed into true anorexia nervosa. Head injury also has been cited as a precipitant (Damlouji & Ferguson, 1985) of anorexia nervosa.

In the setting of a large-scale epidemiological study it has been possible to examine the relationship between anorexia nervosa and physical illness. Two hypotheses were specifically examined:

- (1) that excessive physical illness earlier in life renders an individual vulnerable to the later

development of anorexia nervosa, i.e. should be considered among the risk factors for this condition;

- (2) that acute physical illness can act as a precipitant for anorexia nervosa in at least a subgroup of cases.

Method

Subjects

The subjects of this study were a group of patients fulfilling the criteria formulated by Russell (1970), for anorexia nervosa. This index group were patients who were referred to the Academic Department of Psychiatry at the Royal Free Hospital for the management of anorexia nervosa between 1972 and 1981.

They were compared with two control groups. The first control group was an age/sex matched population chosen at random from the lists of a large local general practice, which was chosen as the doctors routinely recorded details of past medical history when a patient was first seen. The practice served a population similar in social class to our index group. The second control group was female schizophrenic patients admitted to the psychiatric ward of the Royal Free between 1973 and 1983 and under the age of 35 years at the time of admission. This second control group was included because, unlike the first, the patients were referred to a psychiatric department and therefore would have had histories recorded in a similar manner to the index group.

Data collection

For the index group, coded data were derived from the history recorded at the patient's initial assessment interviews and for the schizophrenic control group data were similarly coded from the admission history. For the general practice

control group all relevant information until the time of case note scrutiny was recorded. The data coded included episodes of physical illness until the time of onset of anorexia nervosa or schizophrenia in the two psychiatric groups.

Illnesses were coded into two groups, 'distant' and 'recent'. Distant illnesses were those which developed more than 2 years before onset (or case note scrutiny in the general practice group), and recent illnesses were those which had occurred within 2 years preceding onset.

The criterion for inclusion as a 'distant' illness was that a definite diagnosis was made and that admission to hospital or treatment in a specialist outpatient clinic occurred. Distant illnesses were further subclassified into perinatal illness occurring in the first year of life, operative illnesses which had necessitated operation under general anaesthetic, non-operative illness and chronic illnesses, persistently present for more than 2 years before onset or case-note scrutiny.

The criterion for inclusion as a recent illness was broader, so that all illnesses which might bring about a significant physiological anorexia could be coded. All illnesses were included where it appeared from case-notes that the patient had taken more than 2 weeks off work or school. Thus, for example, glandular fever and severe influenza occurring within 2 years of onset were included even though no specialist treatment had been received. For further analysis, illnesses were classified again according to principal system involved. The fifteen subheadings are shown as part of Table III.

Results

Subjects

Data were collected for 326 patients with anorexia nervosa, 105 general practice controls and 61 schizophrenic controls. The mean age of onset of anorexia nervosa was 18.7 years (s.d. 6.5) and of schizophrenia 22.6 years (s.d. 6.2 years) (*t*-test $P < 0.01$). The mean age of the general practice control group at the time of case-note examination was 19.3 (s.d. 7.5 years), which was not significantly different from the index group.

Distribution of illnesses

Table I compares the number of physical illness episodes amongst the members of the three groups. The anorexic patients were significantly more likely to have had physical illness than both the control groups and are also more likely to have had several episodes than controls. ($\chi^2 P < 0.001$ in each case.)

Analysis of illness episodes

Analysis of episodes of illness in relation to onset (or case-note scrutiny) is shown in Table II. The index group tend to have more episodes of illness, both distant and recent, but the differences do not reach statistical significance when groups are compared on individual categories.

Analysis of episodes of illness according to system involved is shown in Table III. There were no significant differences when specific categories were compared between groups, but a trend for the anorexia group to have more episodes of illness in most categories is noticeable.

Alimentary vs non-alimentary illnesses

Subjects who had had at least one episode of illness in the anorexia nervosa group and general practice group were further examined by classifying illnesses into alimentary and non-alimentary categories. It was hoped thereby to examine whether illnesses which were more likely to have involved disturbances of eating and a physiological anorexia were more associated with the later development of anorexia nervosa. No statistically significant differences were found between the anorexia nervosa and general practice control groups in the ratio of non-alimentary to alimentary illness for either 'recent' or 'distant' illnesses.

Age of onset of anorexia and illness

Finally, an attempt was made to examine whether a history of undue physical illness might be associated with the development of anorexia nervosa in a particular age group as had been suggested by Ryle (1936). A comparison of the index group and general practice control group stratified by age of the subject showed an expected association of more 'distant' physical illness with age in both groups in the older age band. For all ages the excess of physical illness in the anorexia nervosa group reported in Table I occurred. The results did not suggest, however, that anorexia nervosa developing in an older age group was more likely to be associated with a history of undue physical illness.

Discussion

This study has attempted to examine the relationship between a history of physical illness and the later development of anorexia nervosa. Before discussing the findings it is important to examine methodological problems which may have influenced the findings obtained and conclusions which can be drawn.

TABLE I
A comparison of distribution of episodes of illnesses in index and control groups

Number of physical illnesses per individual	Anorexic patients <i>n</i> = 326	GP controls <i>n</i> = 105	Schizophrenia controls <i>n</i> = 61
	%	%	%

The subjects of this study were patients attending a tertiary referral centre for anorexia nervosa. As such they may be chronic, established or unusual cases not wholly representative of all anorexic cases. It is possible that physical illness is over-represented in those referrals. In contrast, the general practice control group was chosen to represent a normal sample of subjects matched for age, sex and similar in social class. However, subjects who had never visited their general practitioner were excluded, implying that this control group would be biased in favouring illness episodes, thus making it more difficult to observe any significant excess of physical illness in the anorexia group, if it existed.

A possible second source of error arises from the different methods of data recording between the hospital and general practice patients. The schizophrenia control group had been inpatients and therefore had histories similar in type to the index group. One problem is that physical illness as an alternative diagnosis is more likely in anorexia

nervosa and therefore may have been recorded more carefully in the anorexia nervosa subjects. This, however, is unlikely to have been an issue in relation to the general practice control group where in addition to routine recording of past medical history, a record of all attendances was kept. There is no reason to believe that clinical history-taking would have been different in the two different settings and so it seems unlikely that an illness of sufficient severity to be classified would have escaped recording in this second control group.

In chronic anorexia nervosa, difficulties may arise in determining accurately the date of onset of the eating disorder, thereby leading to difficulties in determining whether a physical illness preceded or postdated onset. As there was however no significant excess of alimentary vs non-alimentary episodes in the recent illness category, it seems unlikely that this has caused a significant bias.

The major findings of this study then is that there was an excess of physical illness episodes in the

backgrounds of subjects with anorexia nervosa, when compared with general practice and schizophrenia controls. Attempts were made to specify the characteristics of this excess of illness episodes. However, analysis of illness as classified by 'distant' or 'recent', or by system involved did not yield any statistically significant difference between index and control groups. No particular association for illnesses which cause a physiological anorexia was discerned. The attempt to evaluate the hypothesis that there is a particular relationship between physical illness and anorexia nervosa for the older age group found no evidence to substantiate this.

The first hypothesis suggested, that physical illness earlier in life renders an individual vulnerable to later anorexia nervosa, is supported by the findings of this study. While there is an excess of physical illness in the period immediately preceding the onset of anorexia nervosa when compared with controls this excess is not significantly more than that found when examining more distant illness. This suggests that a history of severe physical illness is a non-specific risk factor for anorexia nervosa rather than specifically a precipitant as suggested by the second hypothesis.

There are several possible explanations for this observed association between anorexia nervosa and past physical illness. The first possibility is that there is a direct aetiological relationship in a certain group of patients. This suggestion seems unlikely as one would expect to observe physical illnesses with specific characteristics being particularly linked to the development of anorexia nervosa. In this study no such specific characteristics were observed. A second possibility is that some other factor, possibly genetic, predisposes to the development of physical illness and to anorexia nervosa. Again this seems unlikely as one would expect to find some differentiation within the types of physical illness observed and a higher than expected prevalence of physical illness in the relatives of patients with anorexia nervosa. There is little evidence to support the latter suggestion. Halmi *et al* (1977) report that gastrointestinal disorders are not uncommon in the relatives of patients with anorexia nervosa, while Kalucy *et al* (1977) found maternal migraine to be common. These reports are of interest but do not constitute strong evidence for there being an excessive prevalence of physical illness in the families of anorexics.

A third possibility is that the observed association between physical illness and anorexia nervosa is

mediated through some other factor. Minuchin *et al* (1978) has suggested that relationships in the anorexic's family are characterised by over-protection and enmeshment. It does seem plausible that such a pattern of relationships might be initiated during an episode of serious illness. While it is possible that emotional disorders in such families may present as physical illness and be recalled as such, the explanation that illness triggers potentially pathological relationships within the family, seems the most plausible and warrants further investigation.

Conduct Disorder and Hyperactivity: I Separation of Hyperactivity and Antisocial Conduct in British Child Psychiatric Patients

E. TAYLOR, R. SCHACHAR, G. THORLEY and M. WIESELBERG

The distinction between hyperactivity and conduct disorder was explored in a mixed group of 64 children referred to psychiatric clinics because of antisocial or disruptive behaviour. A semi-structured interview measure (the Parental Account of Children's Symptoms, PACS) proved to have adequate inter-rater reliability, internal consistency and factorial validity. The PACS scales of defiance and hyperactivity, and similar subscales from Conners' Teacher Rating Scale, were tested against laboratory and clinical measures of activity, attention, cognitive performance, psychosocial background and family relationships. The hyperactivity (but not the defiance) scales were associated with greater activity, younger age, poorer cognitive performance and abnormalities on a developmental neurological examination. The defiance (but not the hyperactivity) scales were associated with impairment of family relationships and adverse social factors. It was concluded that a dimension of inattentive, restless activity should be separated from one of antisocial, defiant conduct in children with psychiatric disorder.

Hyperactivity and conduct disorder are frequently present at the same time and in the same people. It is not even clear whether they are genuinely different problems. This paper examines the question.

North American writers on hyperactive children have made it clear that aggression and defiance are frequently the target symptoms for treatment rather than the core symptoms of poor attention and excessive movement (Safer & Allen, 1976; Barkley, 1981). Indeed, the third edition of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-III) states explicitly that non-compliance and bullying are part of the condition of 'attention deficit disorder with hyperactivity'—and, conversely, that many cases of 'conduct disorder' have hyperactivity symptoms (American Psychiatric Association, 1980). Stewart *et al* (1981) reported that two out of three hyperactive children had a conduct disorder as well.

A complementary situation exists in British practice. Hyperactivity is rarely diagnosed, conduct disorder frequently: but overactivity and restlessness are common among the conduct disordered. Thus, Taylor (1979) reported that Conners' Classroom Rating Scale scores of a group of children with the clinical diagnosis of conduct disorder were very similar to those of children diagnosed as hyperactive in the USA.

The extent to which the two problems overlap raises a real question about whether they are in fact distinct. Few studies have sought differences between the hyperactive and the conduct disordered; fewer still have found any; and none have found a sharp distinction between conditions (Sandberg, 1981; Taylor, 1985). Indeed, Quay's (1979) review of classification argued with authority against the use of hyperactivity as a valid construct for the description of behaviour problems. Loney *et al* (1978) found different implications of dimensional ratings of hyperactivity and of aggression; but the ratings were based upon chart records and in principle subject to bias. The issue has usually been examined in terms of categorical schemes of classification, based upon diagnostic rules for allotting children's disorders to one group or another. Such rules are bound to be somewhat arbitrary, inasmuch as most children with one behaviour show the other too. Even before establishing criteria for diagnoses, one needs to determine whether the behaviours (on which the rules are based) are functionally independent.

Accordingly, in this paper we ask whether a dimension of hyperactivity, separate from one of antisocial conduct, is valuable for describing children attending psychiatric clinics.

Method

Subjects

64 boys, aged from 6 to 10 years, were examined; all had been referred to psychiatric clinics in south London for treatment of conduct problems (including aggressive, antisocial and/or hyperactive behaviours). Three clinics co-operated in this study: two child guidance units and the children's outpatient department of a postgraduate psychiatric teaching hospital. The subjects also met the inclusion criteria of living in a family home (and not an institution), and attending normal state schools. All had IQs over 65, none had overt neurological disease or psychotic symptoms. None had had any psychotropic drugs prescribed in the preceding 6 months. They are further described in the section on 'Results'.

Measures

Parental account of childhood symptoms (PACS)

This standardised, semi-structured interview was developed as an instrument for the measurement of children's behaviour problems as seen at home. It is administered by a trained interviewer. Parents are asked, not for their ratings of problems, but for detailed descriptions of what their child has done in specified situations over the previous week. Such situations are defined either by external events—e.g. watching TV, reading a book or comic, playing alone, playing with friends, going to bed, travelling—or by behaviours shown—e.g. crying, worried talk, tempers, fighting with siblings. The interviewers then make their own ratings, on the basis of their training and written definitions of the behaviours to be rated, on a four-point scale of severity (0 to 3) and frequency in the previous week. The judgements of frequency and severity are made independently and according to written criteria. Scores on frequency and severity are then averaged to yield the score for each item.

The recall of the previous week's behaviour is then used as the basis for enquiry about the same situations in the previous year. Frequency, severity, age-inappropriateness and degree of handicap imposed are combined into a single four-point rating of problem severity for each item of behaviour.

In all, 44 items of behaviour are enquired about in this detailed way. Some, however, relate to rare symptoms (e.g. in sexual development) or to symptoms not directly relevant to this study. The remaining items are grouped into three subscales, each of which is averaged to give a metric score ranging from 0 to 3.

The subscales are:

- (1) *Hyperactivity*. This is made up of attention span (time spent on a single activity, rated separately for four different kinds of activity), restlessness (moving about during the same activities), fidgetiness (movements of parts of the body during the same activities) and activity level (rated for structured situations such as mealtimes and car journeys).

- (2) *Defiance*. This scale is composed of items concerning temper tantrums, lying, stealing, defiance, disobedience, truanting and destructiveness.
- (3) *Emotional disorder* is made up from items of misery, worrying, fears, apathy, hypochondriasis, and obsessionality. It therefore relates to overt emotional distress, not to inferences concerning the emotional basis of symptoms.

Classroom behaviour

This was measured with Conners' Teacher Rating Scale (Conners, 1969, 1973). Minor changes of wording were made to increase its acceptability to teachers in England. The modified questionnaire has acceptable reliability and stability over time; and normative values have been established in a normal school population in south London (Taylor & Sandberg, 1984). The scoring system was based on those normative values: factor scores were estimated from the standardised z-scores on those items loading on the 'hyperactivity' and 'defiance' factors, weighted by their factor score coefficients. The scale validly describes children's behaviour problems in classrooms (Sandberg *et al*, 1980; Schachar *et al*, unpublished m.s., 1984).

Psychiatric interview

The interview with the child was carried out in the standard format described by Rutter & Graham (1968). This yields a number of interviewers' ratings of psychiatric symptoms, each on a three-point scale. Factor analysis of the interview has indicated that the first factor to emerge is made up chiefly by the items of overactivity, attention span, distractibility, fidgetiness and social disinhibition (Luk, personal communication). These items were summed to give a scale of 'observed hyperactivity'.

Physical examination

This examination included a scored developmental neurological examination (Sandberg *et al*, 1978) and assessment of minor physical anomalies (Waldrop *et al*, 1968).

Psychological testing

The revised version of the Wechsler Intelligence Scale for Children (short form) was given to all children (WISC-R). In addition, a set of tests was given to measure abilities related to 'attention'. They are described in detail by Thorley *et al* (unpublished m.s., 1984). They included:

- (1) *A Continuous Performance Test (CPT)* of sustained attention (Erlenmeyer-Kimling & Cornblatt, 1978). In this vigilance paradigm, pictures representing playing cards are presented successively by a micro-computer on a TV screen; the child presses a button whenever a stimulus is identical to the one preceding it. The number of correct responses, false positives and false negatives are recorded, and non-parametric measures of observer sensitivity and observer criterion are calculated, based on signal detection theory (Pastore & Scheirer, 1974).

- (2) *A Paired Associate Learning Test* (PAL) (Swanson & Kinsbourne, 1976), in which a verbal response is learned to each of a set of visual stimuli. It is thought to reflect efficient use of strategies in short-term memory.
- (3) *The Porteus Mazes Test* (Porteus, 1947), which is sensitive to an impulsive and disorganised style of problem-solving.
- (4) *A test of Selective Listening for Digits* (SLD), in which one voice has to be listened to in the presence of another and subsequently recalled. This is intended to measure the selective 'filtering' of input on the basis of simple physical cues (Broadbent, 1971).

A composite scale of attention test performance was derived by summing the log- and z-transformed scores on the observer sensitivity measure from the CPT, the percentage success rate on the PAL, the age score from the Porteus Mazes, the selectiveness score from the SLD and the digit span from the same test. The justification for this procedure and the factor analysis of the test battery are described by Thorley *et al* (unpublished m.s., 1984).

Social background factors

These were assessed during the interview with the parents. Social class was defined by the Registrar-General's classification of occupations (OPCS 1970). Family size was defined by the number of children under 17 living in the household. The parental situation referred to the people with whom the child was currently living, and a 'broken home' was defined as any situation other than living with two natural or adoptive parents. 'Previous separations' referred to any spells of 1 month or longer when the child was living away from parents. Institutional care was defined as present when the child had spent any period of his life in a children's home, regardless of the reasons for this and the legal status of the stay.

Family relationships

Family relationships were assessed by standardised semi-structured interview methods based on those described by Quinton *et al* (1984).

Efficiency of parental coping with behaviour problems is asked about for a wide range of potential problems. The interviewer's questioning is directed to the style of coping, not to its outcome, and does not make assumptions as to which techniques are desirable. Rather, efficient responses to children's behaviour are defined as being tailored to the individual child; involving clear goals, a coherent plan and adequate follow-through; being flexible and modified in the light of events; and using pressure appropriate to the child's level of development. Ratings are made (after training) on an eight-point scale ranging from 1 (for very efficient) to 8 (for highly inappropriate responses).

Consistency between parents is separately rated, for each of the problem areas. The scale ranges from 0 (for no disagreements or countermanding) to 3 (for arguments in front of the child or mutual countermanding).

Ratings of expressed emotion are made for the mother's emotional tone when talking about the child. Warmth and criticism are separately rated on scales from 0 (for no warmth or criticism) to 5. The ratings are based on counts of positive and negative comments, content of speech and tone of voice, spontaneity of comments, sympathy for the child's position and interest in the child as a person.

Contact between parent and child is rated by the description of the previous week and all occasions when there were conversations between parent and child (regardless of content) or positive interactions, such as games, that are not merely incidental to child care. Frequency is rated from 0 (for none) to 3 (for interactions every day).

Quality of parents' marital relationship was assessed by the detailed interviewing scheme described by Brown & Rutter (1966). The scale ranges from 1 (for a marriage typified by mutual concern and affection with no long-lasting tension or important quarrels) to 6 (for one with absence of affection and negligible co-operation). The presence of open discord was separately recorded.

Procedure

When referrals were received at the clinics, subjects and parents were offered an immediate assessment by the research team, with the possibility of a trial of treatment in advance of the routine waiting list time for assessment and therapy. Only 83, out of 154 identified, accepted the offer; and a further 19 preferred not to proceed with the assessment after initial discussions. This high refusal rate should be seen as reflecting unfavourable public and media attitudes towards research and physical treatments, as well as the uncertainty of people referred to psychiatric clinics for the first time. Full informed consent was obtained from all those who accepted.

For those entering the study, parents were interviewed by a psychiatrist; the child was interviewed, and then physically examined, by a different psychiatrist; and the child was given psychometric tests by a clinical psychologist. Each assessor was blind to the other assessor's findings, and to other clinical information, until after his own ratings had been made. In 25 cases, the parents' interview was witnessed by an independent assessor, who made his own ratings as a check on the reliability of the technique. School reports and completion of rating scales were independently obtained. Medical records were requested whenever relevant.

After the assessment, the research team met for consensus decision on the five diagnostic axes of the multi-axial version of the 9th edition of the International Classification of Disease (Rutter *et al*, 1976). Diagnostic decisions were based upon all available information, except that the set of tests related to attention were not used as no normative data were available.

Results

Characteristics of sample

Since the self-selection of subjects for the study could have introduced a bias, this series is compared in Table I with

TABLE I
Comparison of subjects with previous clinical series

	<i>Present study</i> (n = 64)		<i>Previous series</i> (n = 68) (Sandberg et al 1978)	
	<i>Mean</i>	<i>(s.d.)</i>	<i>Mean</i>	<i>(s.d.)</i>
Age in years	8.6	(1.7)	8.2	(1.8)
IQ	96.4	(15.5)	96.6	(15.5)
Conners' Parent hyperactivity	10.9	(5.0)	10.7	(5.0)

a previous series of consecutive cases from the outpatient department of the Maudsley Hospital (described by Sandberg *et al*, 1978). Age, IQ, neurological status and symptom levels on Conners' rating scales (using the scoring system given by Conners, 1973) were compared by *t*-tests

and showed no significant differences. Social factors, tested by χ^2 tests, did not differ between the two series. The present sample can be considered representative of boys referred for psychiatric help in this area.

The 90 boys who did not enter the study were not obviously different from those who did. Only limited information was available from initial referral sources. Their age was similar (8.4 years, s.d. 1.9); a similar number came from broken homes (35.6%); and a similar number of their referral letters mentioned overactivity or poor concentration as a specific problem (24.4%; by comparison with 26.6% of those entering the study).

Parental account of children's symptoms: reliability and factor structure

Product-moment correlations were computed for each pair of raters' scores on the scales from the PACS. These indicated an acceptably high level of agreement. For the hyperactivity scale (previous year) the correlations ranged from 0.92 to 0.95; for defiance, 0.89 to 0.95; for emotional disorder, 0.79 to 0.90. For efficiency of parental coping the range was 0.69 to 0.76; for expressed warmth, 0.78 to 0.91; for expressed criticism, 0.79 to 0.86; for father-child contact, 0.79 to 0.96; for mother-child contact, 0.81 to 0.95.

The internal consistency of the scales for behaviour in the previous year was also acceptably good. Cronbach's α was 0.89 for the hyperactivity scale, 0.87 for defiance.

Fifteen of the behavioural items were selected for a factor analysis on the basis of being relevant to the main question of the study (so that developmental and somatic symptoms were omitted), being reliably rated by two interviewers, and having a 0 score present in not less than 10% and not more than 90% of cases. They were then submitted to principal factor analysis with iteration (as maintained in the SPSS

TABLE II
Rotated factor loadings for PACS items of previous year

<i>Symptom</i>	<i>Factor 1</i>	<i>Factor 2</i>	<i>Factor 3</i>	<i>Factor 4</i>	<i>Factor 5</i>

* $P < 0.05$

program package) and rotated according to varimax criteria. Table II shows the solution for the previous-year ratings.

The first factor is clearly one of restless, inattentive, impulsive behaviour ('hyperactivity'). The second is one of non-compliance and tempers ('defiance'), which emerges separately from Factor 3 ('antisocial'), made up of the behaviours of lying and stealing. Emotional symptoms load separately on to Factor 4 ('affective') and Factor 5 ('obsessional'). The item of activity level was split between hyperactivity and defiance factors. Since the orthogonality of factors could not be assumed *a priori*, oblique rotations were also taken. The same number of factors emerged, with the same pattern of variables loading on them: the only differences were in the order of emergence of the factors (and, of course, the exact values of factor loadings).

This analysis gave some support to the distinction between hyperactivity and defiance as separate dimensions of behavioural symptoms. The pattern of factors was very similar for the previous-week ratings: the same factors appeared in the same order. Fuller results on the reliability and factorial validity of the scales are available from the authors.

Home and classroom behaviour and observed activity level

Table III shows the correlations between the previous-year PACS ratings and the Conners teacher rating scales; and between these and the rating of hyperactivity made by the psychiatrist and the observations during psychological testing in the laboratory. Both the teacher and the parent hyperactivity scales significantly predicted the independent clinic measures of overactivity in interview and motor activity during testing. Neither of the defiance scales was associated with laboratory measures of activity.

Home and classroom behaviour and chronological age

There was a significant inverse correlation between the child's age and his PACS hyperactivity ($r = -0.32$; $P < 0.05$) and classroom hyperactivity rating ($r = -0.24$; $P < 0.05$). By contrast, there was no association between age and defiance as measured by the PACS ($r = -0.11$, NS) or by the Conners teacher scale ($r = 0.12$, NS).

Age has therefore been taken into account in the following analyses by the statistical method of partial correlation.

Home and classroom behaviour and developmental measures

Product-moment correlations were substantial between parent hyperactivity and attentional performance ($r = -0.54$; $P < 0.001$) and between teacher hyperactivity and attentional performance ($r = -0.47$; $P < 0.001$); but non-significant between defiance scales and attentional performance. Table IV sets out the partial correlations between behaviour ratings on the one hand; and the full-scale IQ, the attentional performance scale, and the developmental neurological examination on the other hand. In each case, age has been partialled out.

TABLE IV
Partial correlations between behaviour ratings and developmental measures, after allowing for age

	IQ (WISC-R)	Attentional performance	Neurological examination
<i>For all children</i>			
PACS hyperactivity	-0.28*	-0.27*	0.32*
PACS defiance	-0.06	-0.16	0.05
Classroom hyperactivity	-0.42*	-0.29*	0.47*
Classroom defiance	-0.06	0.00	0.05
<i>For those with IQs more than 80</i>			
PACS hyperactivity	-0.30*	-0.26*	0.31*
PACS defiance	-0.17	-0.19	0.09
Classroom hyperactivity	-0.47*	-0.31*	0.50*
Classroom defiance	-0.16	-0.03	0.12

* $P < 0.05$

Correlations, though small, remained significant between the hyperactivity scales and the three test measures, and remained insignificant for the defiance scales. When both age and IQ were partialled out, few significant correlations remained between any of the behavioural scales and the developmental measures. However, the partial correlation between the PACS measure of home hyperactivity and the attentional performance scale was just significant at the 0.05 level ($r = -0.23$) even after both age and IQ had been partialled out.

These results were not the consequence solely of including some children with dull intelligence. Table IV shows that, when the eight children with IQs of less than 80 are excluded,

TABLE V
Partial correlations between behaviour measures and family relationships

	Parental coping	Parental inconsistency	Father-child contact	Mother-child contact	Warmth by mother	Criticism by mother	Marriage quality
PACS hyperactivity	0.10	0.17	0.47*	0.14	-0.16	0.18	-0.09
PACS defiance	0.42*	0.45*	0.19	-0.03	-0.38*	0.40*	0.16
Classroom hyperactivity	0.02	-0.02	0.15	-0.19	0.05	-0.01	-0.12
Classroom defiance	0.13	0.05	0.08	-0.32*	-0.07	0.07	-0.20

* $P < 0.05$

the associations between hyperactivity and impaired cognitive performance and coordination remained positive and specific.

The distinction between dimensions of hyperactivity and defiance was paralleled by that between diagnoses of hyperkinesis and conduct disorder in the ICD 9 scheme. The mean IQ for the seven with hyperkinetic syndrome was 79.7 (s.d. 10.1); for the 42 boys with conduct disorder 95.8 (s.d. 13.1); for the 15 with other diagnoses 108.5 (s.d. 15.5); analysis of covariance with age as covariate indicated a significant difference ($F = 7.6$; $P < 0.05$). The mean scores on the attention performance scale were -4.24 (s.d. 2.16) for the hyperkinetic, -0.04 (s.d. 1.88) for the conduct-disordered, and 1.29 (s.d. 1.36) for the others ($F = 21.4$; $P < 0.01$). The attentional differences remained significant when both age and IQ were entered as covariates ($F = 5.3$; $P < 0.01$).

The children's behavioural scores were also broken down by the presence or absence of background factors relevant to developmental delay. Neither an abnormal obstetric history, nor a history of delay in the developmental milestones of language, mobility and continence, nor the presence of minor congenital anomalies proved to be associated with the level of any behaviour problem.

Behavioural measures and family relationships

The same measures of hyperactivity and defiance at home and at school are related in Table V to the scales of parental

efficiency in coping, consistency between parents, contact between parent and child in the previous week, expressed warmth and criticism by mother, and quality of parents' marital relationship. The measure of association is the partial correlation coefficient after controlling for chronological age. Defiance at home was associated with inefficient coping strategies by parents, inconsistency between parents, less expressed warmth and more expressed criticism. Defiance in the classroom was associated with less contact between mother and child at home. The measures of hyperactivity did not show this pattern of associations: the only significant finding was an *increased* contact between father and child (which may, of course, have been initiated by the child).

Behavioural measures and social factors

The frequency of some background social factors was described in Table I. Table VI presents the means of the behavioural measures for groups differing on these background social factors and also on the country of birth of parents. No significant differences were found on the home measures, nor the hyperactivity measures at school. The only differences were on the teachers' ratings of defiance, where greater severity was associated with lower socio-economic status and with having a parent born in the West Indies.

TABLE VI
Behaviour ratings and social factors

	Parental situation			No. of children			Social class				Parents birthplace				
	Family intact	Broken home		≤2	3	≥4	I & II	III	IV & V			UK	WI	Other	
PACS hyperactivity	0.9	1.0	NS	1.0	0.8	0.9	NS	1.1	0.8	1.0	NS	1.0	0.9	0.7	NS
PACS defiance	1.3	1.4	NS	1.2	1.6	1.5	NS	1.3	1.2	1.6	NS	1.4	1.1	1.4	NS
Classroom hyperactivity	1.5	1.7	NS	1.7	1.1	1.9	NS	1.9	1.4	1.7	NS	1.6	1.9	1.0	NS
Classroom defiance	1.3	1.5	NS	1.2	1.1	2.0	NS	1.3	1.0	2.3	*	1.1	2.3	1.2	*

* $P < 0.05$

NS = not significant.

Adverse events were noted in the history of a number of the children: 14 had been separated for more than a month from one parent only, 19 from both parents. The behaviour scales of the children who had undergone separations were no different from those who had not, when tested by analysis of covariance using age as covariate. Eleven children had had periods of institutional care, and their home behaviour was no different from the others. However, their hyperactivity in classroom (mean 2.3) was significantly greater than that of the others (mean 1.4). Full details are available on request.

Discussion

Is hyperactivity different from antisocial conduct?

The results above give some support to a distinction between two dimensions of disruptive behaviour problems. The classification of symptoms by factor analysis suggests that—at least in this kind of clinical series—items of restless, inattentive behaviour are associated with one another more than with non-compliant, antisocial conduct. However, for such a separation to mean anything it must be capable of predicting relationships with variables other than those which defined the dimensions in the first place. Furthermore, the factor analysis by itself is not conclusive: it is based upon a relatively small number of cases and the number of variables was correspondingly restricted. The key item of activity level was in fact split between the factor we have labelled 'hyperactivity' and that of 'defiance'.

Accordingly, construct validity needed to be tested from a network of potentially important associated variables. The most obvious of these were similar behaviours in different settings. The point is not only that hyperactivity at home showed a modest correlation with that in school, or that defiance did the same; the apparent absence of links between hyperactivity in one situation and defiance in another is as important. Similarly, the lack of a clear association between direct observation of activity and ratings of defiance is as important as the presence of an association with hyperactivity ratings at home and at school. It should, of course, be no surprise that children rated as overactive should turn out to make more movements. Nonetheless, the finding is not a tautology but an approach to validating the concept. There is a distinct pattern of associations with other variables—hyperactivity being related most strongly to neuropsychological test results, and defiance to measures of interaction between family members. The negative results, as well as the positive, suggest that these two constructs have some discriminative validity.

Some possible objections to this conclusion need to be considered. The first is that the preconceptions of the researchers could have led to halo effects and contamination of one measure by another. This certainly cannot explain all the results. Pains were taken to ensure the independence of the different sources of information. The parental measures, the teachers' ratings, the psychiatrist's ratings and the direct observations were all made in ignorance of the results from the others. However, on a few variables there is a chance of contamination: most notably, the measures of family life and relationships were not blind to the accounts of behaviour at home. We do not think that our preconceptions account even for this aspect of the distinction between hyperactivity and defiance, since our original view of hyperactivity—based on pilot studies—was as a non-specific and situation-dependent aspect of conduct disorder. The repeated checks on inter-rater reliability would also have worked against such an artefact.

A second possible objection comes from our choice of a heterogeneous group of boys as subjects. It may indeed be that the associations of hyperactivity with other variables would appear much weaker if we had confined our study to a narrow range of high scores on the hyperactivity measures. But that would not imply that the present findings are in any sense an artefact. Certainly the results cannot be attributed to the group's heterogeneity in IQ scores: they are unchanged by the exclusion of those with low IQ.

Another possible reservation comes from the series being composed exclusively of clinic attenders. Since several centres were involved, we anticipate that the results will be generalisable to other psychiatric settings. We do not assume that the distinction made on clinic attenders will necessarily apply to other groups, such as normal schoolchildren, or girls, or intellectually retarded children, or older or younger children with behaviour disorder. More research will be needed on these populations.

A previous pilot study did not show agreement between different measures of activity in different settings (Sandberg *et al*, 1978). However, the present study should be seen as extending rather than contradicting those findings. It has used more developed measures, and associations may well have been obscured by error variance in less satisfactory instruments. The few positive findings of the previous paper are replicated here: the chief of these was the association between teacher ratings of hyperactivity and a low IQ. While the associations between hyperactive behaviour in different settings are now statistically significant, they are still rather modest

in size. In general, less than a quarter of the variance of hyperactivity in any one situation can be accounted for by other hyperactivity measures. Situational factors are important too.

Is hyperactivity based on attention deficit?

'Attention deficit' can mean a set of behaviours such as frequent changes of activity and impersistence. It can also refer to an impairment of central processing manifest in psychometric tests. In the first sense, attention deficit is clearly bound closely together with overactivity in this population. In the second sense, there appears to be an association between hyperactivity and poor scores on the attentional scale. However, the association between hyperactivity and IQ is just as large; and when IQ is also allowed for, attention deficit is only weakly related to behavioural hyperactivity. The implication is that hyperactivity is indeed associated with cognitive impairment, but of a rather general kind. It may reflect a problem of reduced central processing capacity or of diminished test motivation. It may be that high activity levels impair one's ability to perform well on any kind of structured psychological test. The association might also be accounted for if both hyperactivity and cognitive impairment result from a common cause, such as immaturity of development.

Further research will be needed to determine whether any specific cognitive deficit accounts for the hyperactives' general difficulty in performance tests. This research will have to take careful account of IQ before claiming a specific deficit in the hyperactive. It will not be sufficient merely to exclude the intellectually retarded, for our results indicate that the relation with IQ holds across the whole range of abilities. For the present, one should not regard hyperactive behaviour as a result of, or synonym for, a specific deficit in central processes of attention.

Aetiology of hyperactivity and conduct disorder

It would be tempting to conclude that hyperactivity is rooted in developmental delay, conduct disorder in problems of family life. Tempting, but not yet justified. Association does not prove causal relationship. It remains possible, on this evidence, that defiant, antisocial behaviour evokes inefficient and inconsistent coping strategies from parents, and causes coldness and hostility; rather than being caused by parental styles or genetically linked to them. It is just as likely from these data that teachers'

perceptions of antisocial behaviour are conditioned by their pupils' social class and ethnic background as that those factors cause antisocial behaviour. These findings are only clues to further research. They do suggest that psychological and social factors in children's conduct problems would be obscured if hyperactive behaviour were included as evidence of conduct disorder; and that neuropsychological studies should not include defiant or disruptive behaviour as evidence for the presence of hyperactivity.

Hyperactivity in the classroom showed only one significant association with the range of background factors examined: a previous episode of institutional care. This is nonetheless noteworthy, in view of previous findings on the consequences of institutional care. Tizard & Hodges (1978) reported that there were some long-term consequences of life in a children's home, even years after leaving it; notably, the children were hyperactive and inattentive at school but not at home. Since this finding is closely paralleled by our own, it directs interest towards the question of whether some kinds of close personal interaction are a necessary condition for the development of the normal modulation of activity and attention.

Implications for classification

The associations that we have reported have related to a conceptual framework of dimensions of behaviour disturbance on which each individual can meaningfully be ranked. This has only indirect implications for a categorical system of description such as the first axis of the International Classification of Disease. Inasmuch as they appear to be separate problems, it makes sense to have separate categories for pure hyperactivity and pure conduct disorder. However, most cases show a mixture of the two problems. Their classification is doubtful, and analyses of this paper do not help. Rather one will need to know how cases cluster on these dimensions, and the predictive value of such groupings. The application of cluster analysis to this question will be reported separately.

Regardless of what scheme of classification is adopted, clinicians should recognise both kinds of problem and include them both in diagnostic formulations. Though the behaviours are often present together, they have different implications. They are likely to require different kinds of treatment. Management will be less clear if the two problems are confounded into one label, whether that be 'conduct disorder' or 'attention deficit disorder with hyperactivity'.

Conduct Disorder and Hyperactivity: II

A Cluster Analytic Approach to the Identification of a Behavioural Syndrome

E. TAYLOR, B. EVERITT, G. THORLEY, R. SCHACHAR, M. RUTTER and M. WIESELBERG

Sixty boys, aged from 6 to 10 years, were studied after their referral to psychiatric clinics for antisocial or disruptive behaviour. Their scores on reliable measures of hyperactivity, defiant behaviour, emotional disorder and attention deficit were taken for the home, school and clinic settings; and subjected to two techniques of cluster analysis. Both gave a similar set of clusters, one of which had high scores on all measures of hyperactivity and attention deficit. Membership of this cluster was associated with a lower IQ, a younger age of problem onset and referral, an abnormal neurological examination, a history of developmental delay, smaller family size, poor peer relationships and a high rate of accidental injuries; and it predicted a good response to stimulant medication in a controlled trial. Other research on the classification of hyperactivity is discussed, and proposals are made for the criteria of a rather narrow definition of 'hyperkinetic conduct disorder'.

There is dispute even about the existence of a hyperkinetic syndrome. All diagnostic schemes include such a category, but there is serious disagreement about its definition and how frequently it should be applied. Is it a rare condition, usually encountered in the intellectually handicapped or epileptic (Rutter *et al.*, 1970a); or is it among the commonest of the psychological afflictions of childhood, affecting some 5% of the normally intelligent (O'Malley & Eisenberg, 1973)?

The definitions of the major current schemes reflect the diversity of views about what kind of condition should be recognised. The third edition of the American Psychiatric Association's Diagnostic and Statistical Manual (DSM-III) includes a condition of 'attention deficit disorder with hyperactivity' (ADD-H), for which the requirements are the presence of developmentally inappropriate overactivity, inattention and impulsiveness (APA, 1980). Other problems may also be present, but in that case one diagnoses the corresponding conditions as well. The ninth edition of the World Health Organization's International Classification of Diseases (ICD-9) also includes a condition termed 'hyperkinetic syndrome'. Its essential feature is poor concentration, and 'extreme' overactivity is associated (Rutter *et al.*, 1976). However, ICD-9 requires, more than the presence of hyperactivity symptoms, the absence of any other psychiatric

condition that could give rise to this behaviour. If both hyperactive and aggressive behaviours are present, for example, one must judge which is primary and make one diagnosis only. The DSM-III condition is common, the ICD-9 disorder is rare. Neither approach is of demonstrated superiority.

The uncertainty is a part of a wider problem of classification. Every child psychiatric service encounters many children who are referred because they have serious problems of social adjustment, are disruptive at home or school and fail to make friends or to keep rules or to learn. Many, but not all, seem wretched; many, but not all, seem chaotic and restless in their behaviour. Some suffer under social adversity, some come from seriously disordered families, some have been delayed in the normal course of neurological development. Their problems are many and diverse. Where hyperactivity is a common diagnosis, it is regarded as heterogeneous; where conduct disorder is common, its diversity is no less marked. Is there order in this heterogeneity?

We have argued in Part I that hyperactivity should be seen as a different kind of problem from defiant or antisocial behaviour. It could be thought of as a dimension of psychological symptoms, present to a greater or lesser degree in many disturbed children, and associated with cognitive impairment and poor sensorimotor coordination. (This was not a contribution to typology, but to dimensional classification.)

In Part II we examine the extent to which there is a natural distinction between a category of hyperkinesis and other conduct disorders. We have applied techniques of cluster analysis (Everitt, 1980) to children's scores on reliable, independent measures of behaviour and attention. The resulting groups are then compared, to determine whether they differ in potentially aetiological factors and in short-term response to treatment.

Method

The subjects, measures and procedure of this study have been described in Part I. Here we describe only the aspects unique to this part.

Subjects

From the 64 original boys who had received full assessments after referral for antisocial or disruptive behaviour, 60 were included in this part of the study. The remaining four had been judged to show no behavioural abnormality; their referral reflected inappropriate concern. It was thought desirable to exclude them from a classification of cases that was based on the child's mental state. Thirty-eight of the subjects accepted an offer of a trial of stimulant medication, of which the full results will be reported elsewhere (see below).

Measures

The measures chosen as the raw material for the cluster analysis were intended to describe key areas of the child's current psychological state. They cover behaviour at home, at school and in the clinic. They refer to the symptom domains of *hyperactivity*, with the Parental Account of Children's Symptoms (PACS) hyperactivity scale, Conners' Teacher Rating Scale (TRS) hyperactivity factor, and psychiatric interview hyperactivity scale; *conduct disorder*, with PACS defiance and TRS defiance; *emotional disorder*, with PACS emotional disorder, TRS anxiety and psychiatric interview 'depression' rating; and *attention deficit* with the composite 'attention performance' scale from a battery of psychometric tests of different aspects of attention.

Peer relationships were assessed during the PACS interview. Two different kinds of problem were rated from the parents' account: the first, 'isolation', refers to children who are not part of a peer group, do not have friends and do not take part in group activities; the second, 'unpopularity', refers to negative interactions with peers such as bullying or being taunted. Both can, of course, be present for the same person. Accident-prone behaviour was rated from accounts of episodes of recklessness, lack of appreciation of danger, and minor injuries. Accidents were defined as non-deliberate injuries that necessitated hospital treatment (including attendance at casualty departments).

Three measures were taken to determine short-term outcome. The first was a five-point clinical global rating scale made as consensus judgement by the research team

after each treatment period. 'Clinical global response' indicates that the score was at least one point better after drug treatment than after placebo for that case. The second measure, the 'hyperactivity response', was defined as a reduction of 50% in symptoms, by drug as against placebo, on either the PACS hyperactivity scale or the Conners teacher hyperactivity factor (or both). The third measure, 'marked clinical improvement', was present when the 'clinical global response' was positive *and* the child was given the maximum change rating of 'much improved' while on drug.

Procedure

After the initial assessment had been completed, 38 of the children went on to a trial of methylphenidate against placebo, in a double-blind cross-over design with random allocation to receiving methylphenidate first or placebo first. Each treatment period lasted for 3 weeks, with a washout period of 1 week between them. Measures were repeated at the end of each treatment period. A full description of the trial and its outcome is given by Taylor *et al* (1986).

Analysis

Cluster analysis refers to a diverse set of techniques for the collection of cases into groups in such a way that cases in the same group are similar in some sense, and dissimilar from cases in other groups. Two methods were applied: Ward's method and the method of complete linkage, both of which are described in detail by Everitt (1980). These two methods were chosen from the many available because a number of simulation studies have found them to be amongst the most satisfactory of clustering techniques. Since they gave very similar solutions, the clusters found by Ward's method were then compared on a range of dependent measures from the initial assessment and the post-treatment evaluations (using analysis of variance for the metric measures and χ^2 for the categorical).

Results

Cluster analysis

The two methods of cluster analysis yielded very consistent results. As always with clustering techniques, it is difficult to answer the question of the appropriate number of groups to consider. Consequently, in the absence of any completely satisfactory statistical test for number of groups, the four-cluster solution was chosen on grounds of clinical relevance and because of the very high agreement between methods. Only six cases were classified into different groups by the two procedures: there was total agreement for the other 90%.

The separation of the clusters was clear. Figure 1 shows the profile of mean scores of the four clusters on the variables from which they were derived. The scores are given after z-transformation so as to be comparable in range. One cluster (H) was composed of children with high scores on the hyperactivity scales in all three situations, poor scores

on attention performance, and less evidence of overt emotional disorder. It was made up of 15 cases, 25% of the total. It was clearly very similar to a nuclear definition of hyperactivity.

Cluster C contained 21 cases. It was characterised by an absence of high scores on most variables, but was high on the teacher's ratings of defiance (and, to a lesser extent, hyperactivity) in the classroom. Children in this group appeared to have a situation-specific problem of conduct.

Cluster A (13 cases) was high on teacher and parent measures of emotional distress, but not on 'depression' as rated by the examining psychiatrist. Hyperactive and defiant behaviours in the classroom were both low.

Cluster D (11 cases) was notable for high scores on 'depression' during psychiatric examination.

Both analyses showed the same pattern when the number of clusters was changed. In a three-cluster solution A and D were fused into one, larger group of emotionally disordered children. In the two-cluster solutions this group was joined with C, while H remained separate. When the number of clusters extracted was increased to 5, C broke down into two groups (distinguished by high or low scores on teacher hyperactivity). The most robust feature of the classification was therefore the appearance of the group of pervasively hyperactive and inattentive children (H).

Comparisons of clusters: developmental measures

The four clusters were compared by analysis of variance, with cluster membership as the independent variable and age, IQ and developmental neurological examination as dependent variables. Results are given in Table I. Significant differences existed between the clusters: the H group (of hyperactive children) were younger when referred, had lower IQs and showed more sensorimotor uncoordination. Since the neurological examination was not age-standardised, analysis of covariance was carried out for this measure, with age as covariate. The difference between groups was still significant ($F=3.4$, $P<0.05$).

Table II shows the associations between clusters and the presence or absence of a diagnosis on Axis 2 (developmental disorders) of the multi-axial version of ICD-9; of a history of developmental delay or of pre- or peri-natal difficulties; of more than three minor congenital anomalies; and of an early onset of the psychiatric symptoms. For these comparisons, clusters A and D were combined into a single 'emotional disorder' group, in order for numbers to be large enough for testing with χ^2 tests.

The hyperactive children in cluster H were more likely to have a history of a delay in motor and language development, and current evidence of delay in motor development or language development. It is of interest that the children in group C, identified as showing behaviour problems only at school, had a high rate of a different problem—specific delay in reading ability. Children with emotional disorders (A and D) had little evidence of developmental problems. Group H also showed an earlier onset of psychiatric disorder.

Comparisons of clusters: family relationships

Table III shows the mean scores of the clusters on the interview measures of family life and atmosphere; and the results of comparisons by one-way analysis of variance. There were, in general, few differences. There was a slight tendency for the hyperactives to have more contact with their fathers than the other groups, among the 46 who had fathers or stepfathers at home. In the same 46, the parents' marital relationship showed slightly more problems where the children had emotional disorders (A and D) than in cluster C, where there were few behaviour problems at home. However, these differences are not supported by overall significant differences, and will not be interpreted.

Comparisons of clusters: psychosocial background

The children in the different clusters showed no significant differences in socio-economic status: the father or principal breadwinner was in manual occupations in 33.3% of cluster H, 52.4% of C and 45.8% of A and D combined ($\chi^2=1.3$, NS). There was no difference in whether the child's parents had been born in the UK, the Caribbean nations or elsewhere ($\chi^2=2.2$, NS); nor in the presence of a history of institutional care ($\chi^2=2.4$, NS). Periods of separation from both parents for more than a month had been present in 23.8% of cluster C, 33.3% of H and 29.2% of A and D combined ($\chi^2=3.8$, NS). Family size was indexed by the number of children under 17 at home: this was three or more for 38.1% of cluster C, 13.3% of cluster H, 54.2% of clusters A and D combined ($\chi^2=6.5$, $P<0.05$).

Relationships of clusters to clinical diagnoses

There was considerable overlap, but not complete agreement, between the typology produced by this analysis and that of conventional diagnostic schemes. The ICD-9 scheme yielded seven children with the diagnosis of 'hyperkinetic syndrome'; every one of them had been classified into cluster H (the remaining eight in this cluster being all diagnosed as 'conduct disorder'). The more frequent diagnosis of 'conduct disorder' was more heterogeneous (18 in cluster C, eight in H, eight in A, six in D).

'Attention deficit disorder with hyperactivity' was frequently diagnosed in the DSM-III scheme. It too was a heterogeneous category in the terms of our present clustering: 14 cases came into C, 13 into H, five into A, three into D. It will be noted that all but two of the cases in cluster H met the DSM-III criteria. Figure 2 displays the relationships diagrammatically.

Comparisons of clusters: response to medication

Table IV sets out the percentages in each cluster who responded to methylphenidate according to the criteria outlined in the 'Methods' section. Cluster membership was a significant predictor of the pharmacological response to methylphenidate. Non-pharmacological aspects of response

FIG. 1. Symptom scores for different clusters.

The profile of each cluster is shown on nine baseline variables, each of which has been transformed to a z-score for comparability. In each case, a positive score indicates a higher degree of pathology than the average for all cases.

Variable 1: Hyperactivity at home (from PACS interview).

Variable 2: classroom hyperactivity (from teachers' rating scale).

Variable 3: hyperactivity in psychiatric interview.

Variable 4: performance score on attention tests.

Variable 5: defiance at home.

Variable 6: classroom defiance.

Variable 7: emotional disorder at home.

Variable 8: classroom anxiety.

Variable 9: depression in psychiatric interview.

TABLE I
Clusters compared on developmental measures

Measure	Cluster				Significance	Significant pairwise comparisons
	H (n=15)	C (n=21)	A (n=13)	D (n=11)		
Age (mean, in months)	79	111	107	110	*	H<C, A, D
IQ (mean)	84.5	99.3	101.8	99.2	*	H<C, A, D
Neurological examination (mean)	20.7	6.5	4.5	7.2	*	H>C, A, D

* $P<0.05$ by one-way analysis of variance between the four clusters.

Note Pairwise comparisons made by Newman-Keuls test.

Fig 2 Cluster membership and clinical diagnosis. The figure represents each cluster as a circle, subdivided according to the clinical diagnoses applied to cases in each cluster, for ICD-9 and DSM-III separately.

(such as the effects of suggestion, attention or regression to the mean) were controlled for, since all measures referred to the difference between drug and placebo treatments.

The group of children showing 'marked clinical improvement' obviously needs to be identified for practical purposes. Of the 38, 11 showed this marked response and of those 11, eight were in cluster H. Only three of the 27 who showed a lesser response were in cluster H. Membership of this 'hyperactive' cluster therefore predicted 73% of the marked responders, while non-membership predicted 89% of those with smaller, or no responses. This is accurate enough to be clinically useful.

TABLE IV
Response to medication in different clusters

	H (n = 11)	C (n = 14)	A + D (n = 13)
Clinical global rating			
Responders	90.9%	57.1%	30.8%
Non-responders	9.1%	42.9%	69.2% *
Hyperactivity response

Non-responders	27.3%	50%	76.9% *
Marked clinical improvement			
Present	72.7%	14.3%	7.7%
Absent	27.3%	85.7%	92.3% *

* $P < 0.05$, by χ^2 test.

TABLE V
Comparisons of clusters in the frequency of complicating symptoms

	Cluster		
	H (n = 15)	C (n = 21)	A + D (n = 24)
Adequate peer relationships	13.3%	38.1%	33.3%
Isolated or unpopular	20.0%	23.8%	45.8%
Isolated and unpopular	66.7%	38.1%	20.9% *
Presence of accident-prone behaviour	66.7%	9.5%	25.0% *
Accidents requiring hospital treatment:			
none	33.3%	66.7%	50.0%
one only	20.0%	23.8%	37.5%
more than one	46.7%	9.5%	12.5% *

* $P < 0.05$ by χ^2 test.

Comparisons of clusters: complicating symptoms

Certain behaviours enquired about during the assessment interviews were conceptualised as possible complications of psychological disorder. These were a propensity to accidents and an impairment of relationships with peers. Table V shows the association between these variables and cluster membership. All showed significant differences between clusters, with the 'hyperactives' of cluster H being

particularly likely to be isolated and unpopular in their relationships with other children, to be accident-prone and impulsive in behaviour, and actually to have suffered a high frequency of accidents serious enough to have required treatment at a hospital.

Discussion

Is there a syndrome of hyperactivity?

The cluster analysis identified a group of pervasively hyperactive and inattentive children among those presenting with antisocial or disruptive conduct. In itself this gives some support to the concept of a hyperactivity syndrome. For such a category to be clinically useful, however, it must be capable of predicting associations other than those which defined the group in the first place (Rutter, 1978). We have found that it does so.

Some of the associations are unsurprising, given that the cluster analysis had identified an inattentive, hyperactive group in the first place. Since they show this kind of cognitive impairment, it is perhaps to be expected that they would also show the delay in cognitive abilities that is indexed by a low IQ. The high frequency of signs of sensorimotor uncoordination, the history of developmental delay, and the presence of developmental disorders are in line with this, and contribute to the coherent pattern of findings. The importance of this pattern for development is underscored by the very high frequency of accidents (presumably as a result of impulsiveness) and of poor relationships with other children.

The younger age of the children in the hyperactivity group might reflect either a tendency for early onset and early referral, or a trend for the problems to change or lessen as children mature. It is possible, for instance, that specific reading retardation in later childhood is the heir to earlier delays in language and motor development. Longitudinal and epidemiological studies will be needed to answer these points. However, many of the findings are not attributable simply to the children being younger. Low IQ is not a result of greater youth, as of course the measure is age-standardised; abnormal neurological examination is not, since age was allowed for in the analysis; aspects of the history such as early onset and late milestones suggest that the differences between groups were present at an early age; the ability of hyperactivity to predict the response to stimulants is not mediated by age (Taylor *et al*, 1986).

Indeed, the short-term response to methylphenidate medication is the most persuasive

validation of the concept of a subgroup of hyperactive children. Membership of cluster H was a strong predictor of a good response. This must be seen in the context of previous findings that available measures predict stimulant response only weakly and doubtfully (reviewed by Barkley, 1976; Taylor, 1983). Furthermore, the ICD-9 and DSM-III diagnoses performed less well as predictors of response, showing no significant relationship with the measures of clinical global rating or of hyperactivity response (Taylor, 1983).

Relationship to other clustering studies

We are not aware of any previous use of cluster analysis to answer this particular question of the existence of a syndrome of hyperactivity. There have, of course, been previous attempts to use statistical methods to generate a taxonomy of schoolchildren's disorders (reviewed by Achenbach & Edelbrock, 1978). Results from these are somewhat conflicting — as is, perhaps, to be expected in that the methods have been applied to very differing series of heterogeneous clinical problems. Lessing *et al* (1981) reported a hierarchical cluster-analytic method, based on the product-moment correlation coefficient as the index of similarity, applied to a parents' behaviour checklist. One of the 15 clusters identified comprised over-reactive, distractible, clumsy, children with low tolerance of frustration. This was separate from 'aggressive, destructive, violent', 'academically disabled' and 'sociopathic' clusters, and is clearly made up of hyperactive children. On the other hand, Lessing *et al* (1982) applied the further strategy of choosing clusters which replicated across different samples, and reported seven groups with different profiles: one of them combined hyperactive and aggressive symptomatology into an 'aggressive, overactive' group. Furthermore (and rather surprisingly), a 'schizoid, withdrawn' group had equally high scores on hyperactive symptomatology.

Other studies seeking to establish typologies of behaviour problems have sometimes found a hyperactive group separate from other antisocial disorders (Patterson, 1964; Edelbrock & Achenbach, 1980); sometimes a common group of acting-out problems including both hyperactivity and other antisocial problems (Lorion *et al*, 1974; Langner *et al*, 1974). These contradictory findings might be seen as reflecting either the lack of a secure distinction between hyperactivity and other behaviour problems, or the limitations of the methods used. They are based on simple checklists concerning styles of behaviour, with consequent ambiguities of meaning

and problems of interpretation. By contrast, the current study is based on reliable measures from several different sources. Our numbers, however, are rather small. For this reason we do not address the more general question of the classification of psychological disorders. Our division of conduct disorders into the hyperkinetic, those confined to the classroom (often with educational failure) and those associated with emotional disorder (perhaps further divisible into anxiety- and depression-based disorders) has an obvious clinical appeal; but can only be a clue for future research.

Relationship to other studies of hyperactive children

A number of investigations have approached the question of validation by comparing those diagnosed as hyperactive with normal controls (Taylor, 1985), or children diagnosed as conduct disordered with normal and emotionally disordered controls (Rutter *et al.*, 1970b). Few have made comparisons between different types of disturbance of conduct, yet such studies are crucial for the definition and understanding of syndromes.

A previous clinic study from this Institute found the pervasively hyperactive to differ from matched psychiatric controls in ways that, like the present findings, pointed towards a developmental origin—namely early onset, inaccurate psychometric test performance, and sensorimotor uncoordination (Sandberg *et al.*, 1978). The present study has produced comparable results through a rather different route.

Stewart *et al.* (1981) and August & Stewart (1982) have presented two analyses of a series of children referred for psychiatric help. The first of these found that children with hyperactivity, but no other conduct disorder showed evidence of cognitive impairment by comparison both with the aggressive and with those with mixed aggression and hyperactivity. The criterion for identification was parental report solely. That study is therefore in line with our finding, in a companion paper, that the parental account of hyperactivity (but not of defiance) was associated with cognitive and neurological immaturity. The second of the papers from the Iowa group synthesised several sources of information into a definition of pervasive hyperactivity (August & Stewart 1982). Those who showed pure hyperactivity in this sense were generally similar to those who also showed an aggressive conduct disorder—except that those few with subnormal IQ scores showed a history of developmental disturbances. This is no contradiction to our present findings. In the first place, the dependent measures for the comparison

were those of putative aetiological factors and social background. We too have found that these measures do not distinguish clinical groups: the causes remain unknown. In the second place, the distinction between 'pure' and 'mixed' hyperactivity does not emerge from our analysis. Our group of pervasively hyperactive, inattentive children also score highly on measures of defiance and antisocial behaviour. 'Pure' hyperactivity seems a rare phenomenon at our clinics, and we have not yet identified it as a natural group.

Firestone & Martin (1979) also used the strategy of comparing a pervasively hyperactive group with clinical controls. The 'behaviour problem' controls in this case may in fact represent rather similar children: they were those for whom observers disagreed about whether or not they were hyperactive. Objective testing, however, did not show them to be any less active or more impulsive. The only difference between these groups—but an important one—was in the poor attention displayed by the hyperactive during psychological testing. The finding adds credibility to our identification of a group of pervasively hyperactive children who were also inattentive. The lack of other differences between their clinical groups is not in opposition to the present study, for they used a very different set of measures that did not include developmental or outcome variables.

Campbell *et al.* (1977) followed up a group of children, identified in a day nursery, until they had entered elementary school. The children with adverse outcomes at follow-up tended to be those who had previously displayed a lack of situation specificity and had been hyperactive in home and nursery alike. A study by Schleifer *et al.* (1975) has also suggested a worse outcome in later childhood for preschoolers with pervasive hyperactivity than with other behaviour problems.

Schachar *et al.* (1981) identified pervasively hyperactive children on the basis of questionnaire ratings from an epidemiological survey of 9-year-old children. They found a pattern (by contrast with a group of children with different problems) of poor cognitive test performance, lower socio-economic status and adverse prognosis. Their finding that hyperactivity predicted the outcome of a conduct-disordered group is supported by Thorley's recent follow-up of grossly overactive child patients with matched psychiatric controls (Thorley, 1984). It can be seen as the complement to the finding by Loney *et al.* (1978) that aggressive conduct disorder predicted the outcome of a hyperactive group. The combination of problems is likely to be particularly important. Indeed, McGee *et al.* (1984) have recently reported

results from an epidemiological survey that give direct support to this thesis, albeit on the basis of small numbers that may have been further biased by missing data. Children identified by teachers and parents as having both the problems of hyperactivity and conduct disorder were more prone to later behaviour disturbances, reading retardation and psychiatric referral than were those with only one of the problems.

In short, recent studies on pervasively and severely hyperkinetic children suggest that they are validly to be distinguished from other psychiatric categories in their prognosis and in their link with cognitive and motor immaturity. By contrast, studies of widely or loosely defined hyperactivity have found little discriminative validity in the idea (Sandberg, 1981; Ferguson and Rapoport, 1983; Taylor, 1985).

Towards diagnostic criteria

We suggest that the heterogeneous diagnoses of 'conduct disorder' (in ICD-9) and 'attention deficit disorder with hyperactivity' (in DSM-III) can be further refined. A substantial minority within both needs to be separately identified. Inclusion criteria for this 'hyperkinetic conduct disorder' group could be:

- (1) pervasive overactivity and restlessness, that is evident across two or more of the situations of home, classroom (or nursery) and clinic (or laboratory)
- (2) impaired attention, detected either by psychometric tests or by directly observed inattention and distractibility in behaviour
- (3) absence of overt symptoms of severe anxiety or other emotional disorder
- (4) presence of severe degrees of persistent non-compliance, aggression or destructiveness

A group defined in this way is likely to be composed of children with other evidence of developmental delay, at risk for accidental injury and with unsatisfactory peer relationships. Many, but by no means all, will have fitted the description of 'hyperkinetic syndrome' in ICD-9. They are likely to respond very well to stimulant drugs, at least in the short term. Longer term outcome, efficacy of other treatments and aetiology will need further research.

The first two criteria will have the effect of excluding many children at present regarded as 'hyperactive' in countries following North American diagnostic usage. It is unclear whether children, who meet the first three inclusion criteria but show no antisocial behaviour, should be given the same diagnosis. In present knowledge, outcome data

suggest that they be categorised in a separate group of pure 'hyperkinetic disorder'.

Acknowledgements

We are indebted to the staff and clients of The Maudsley Hospital Children's Department, Brixton Child Guidance Clinic and Camberwell Child Guidance Unit and the pharmacist and pharmacy staff of the Maudsley Hospital. The study was partially funded by a grant from CIBA Ltd; Dr Schachar was supported during this period by a fellowship from the Medical Research Council of Canada.

(Accepted 17 February 1986)

Severe Self-Mutilation Among Kenyan Psychotics

Four case reports are presented of psychotic patients seen in clinical practice in Nairobi over a period of one year, who inflicted serious bodily harm to themselves during that period. Possible psychopathological basis for this self-damage is briefly considered. A review of the literature reveals paucity of similar reports from Africa and the third world. Reasons for this paucity are hard to come by.

Deliberate self-harm, as seen in psychiatric practice, tends to fall into two broad categories—a mild form usually associated with attention-seeking manipulative behaviour, and a severe form usually occurring in psychotic states. The former tends to occur in young individuals with neurotic or personality disorder. In the latter category the patients may be acting under some delusional belief or they may be obeying auditory hallucinations commanding them to do something which may be injurious to them. Rarely are modalities other than auditory involved. The delusions often involve beliefs that certain parts of the body are either deformed or causing the subject some trouble and should therefore be removed (Standage *et al*, 1974). A rather rare cause of self-mutilation is masochistic sexual behaviour. Schott (1973) has described self castration due to sadistic impulsive perversion and Thompson & Abraham (1983) have reported two rare cases of male genital self-mutilation following paternal death.

Severe self-destructive behaviour is rarely reported from the African continent and the third world in general. This raises certain basic questions such as (a) Does self-mutilation occur at all in these countries? (b) If so, is it in any way different from that seen in the Western countries and finally, (c) Are there any cultural beliefs which either protect or aggravate such behaviour?

Below, we report four cases of severe self-mutilation seen by us during the year 1984. The first three were seen at the Government Mental Hospital (Mathari) and the last at our National Teaching Hospital (Kenyatta National Hospital).

Case reports

Case 1

A 35-year-old inpatient former police constable who had been admitted several times to Mathari Hospital with a diagnosis of schizophrenia presented as an emergency with severe bleeding half an hour after he had extracted his four

lower incisors. Twenty days later he extracted a further six teeth from his lower jaw and continued to self-mutilate his gums with any hard object he would come across. A week later he attempted to hang himself with a blanket but was rescued by a nurse.

On examination he had extensive lacerations of gums and adjacent soft tissues, leaving ridges of lingual and buccal plates bare. Curettage to remove necrotic tissues, alveolectomy and stitching of buccal/labial and lingual flaps was done.

The patient continued removing stitches and developed osteomyelitis. He voluntarily stopped mutilating himself and made a good recovery but remained thought-disordered and aggressive to other patients. He would give no explanation for his actions.

(NB While this paper was being prepared the patient, by means of a sharp pointed piece of metal, dug a hole into his right flank up to the kidney and bled to death).

Case 2

A 16-year-old housemaid was admitted at midnight with a 2 week history of aggressive behaviour, insomnia and refusal to feed.

One hour after admission the patient was found to have bitten off one-third of her tongue which was found on the floor. The remaining stump was sutured, haemostasis achieved and she was put on antibiotics. The patient removed the stitches from her tongue and left the wound gaping. She denied being depressed or having been mistreated by her employer. She did not give any motive for her actions. There was no history of epilepsy in the patient or her family nor was she ever observed to have fits. After 3 weeks' observation, a diagnosis of schizophrenia was made and she was put on depot phenothiazines. She made a satisfactory recovery and was discharged through the out-patient psychiatric follow-up clinic.

Case 3

A 30-year-old childless housewife was admitted to the maximum security section after allegedly having murdered her mother-in-law. After 2 years as an inpatient, she developed suicidal tendencies although she denied being depressed. She threw herself from the roof of the ward and

sustained multiple fractures of both lower limbs. Her right foot became gangrenous and had to be amputated. On recovery, she began mutilating her breasts with any sharp object she could get; later, she went on to self-mutilate her genitalia and sustained a third-degree tear. She talked of being worthless since she could not give birth, hence she had no use for the organs she kept mutilating. There was no history of psychiatric illness in the family. A consultant psychiatrist had diagnosed paranoid schizophrenia and put her on appropriate treatment but she has continued to mutilate her external genitalia.

Case 4

A 24-year-old man presented as a surgical emergency with a deep cut into the shaft of the penis which he could not explain. He was a lonely and withdrawn single and unemployed young man with minimal education. He had no girl friend and lived with his elderly parents in the slums of Nairobi. At interview, he revealed that he had attempted to amputate the penis because some voices kept telling him to do so. He believed that the penis was useless to him. Surgical repair of the penis was done and he made satisfactory recovery on oral phenothiazines.

Discussion

Self-mutilation in psychotic patients is not rare in the West (Greilshamer & Groves, 1979), though we could not find any case report from the African continent. Reports of oral self-mutilation are predominantly male (Mendez *et al*, 1972; MacLean & Robertson, 1976; Greilshamer & Groves, 1979; Pattison & Kahan, 1983; Rada & James, 1982). This is surprising in view of the reported excess of self-damaging behaviour in women. Our cases show no specific pattern either by age, sex, or site, except that two mutilated their mouths and two their genitalia. In either category, one was male and other female. Genital self-mutilation has been associated with unresolved sexual conflicts (MacLean & Robertson, 1976). Symbolically, oral self-mutilation might, in theory, be considered to represent a desire to avoid saying something which is stress-provoking. This would be particularly so in case number 2. In case number 3 there may be severe social pressures. The social and cultural stigma associated with infertility in Africa in general and Kenya in particular does sometimes lead to suicidal attempts but not to self-mutilation, in our experience.

Most of the published reports stress the surgical management and there is very little said about the psychiatric management (Mendez *et al*, 1972; Engelman *et al*, 1974; Standage *et al*, 1974). This is a pattern which should be corrected. Once the emergency surgical management has been carried out, urgent psychiatric referral is essential (Standage

et al, 1974). The majority of such cases will probably turn out to be psychotic, and should therefore benefit from neuroleptics. There will, however, be a small minority of personality and neurotic disorders (Thomson & Abraham, 1983) who will benefit from psychotherapy, as do the majority of psychotics once insight has been restored.

With regard to the questions raised earlier in the second paragraph of this paper, although we have not found published reports on this subject, the occurrence of four cases within a period of 1 year in Nairobi alone (population approx. 1 million) suggests that severe self-mutilation may be occurring as commonly in our setting as in the more developed Western countries. From our series the pattern, mode and severity of such self-destructive behaviour does not differ much from reported cases in the West. We were unable to find any cultural beliefs which have an effect on such behaviour, and overall one is impressed more by the similarities across the cultures than any differences.

It is the belief of the present authors that 'detrification' has less influence on manifestations of psychotic illness but in neurotic disorders the situation may be quite different. Earlier psychiatrists in Kenya (Gordon, 1936; Carothers, 1947) had forecast increased psychiatric morbidity with the erosion of traditional coping mechanisms, such as the extended family, resulting from urbanisation and western style of living. All our cases, however, had lived a substantial part of their lives in rural Kenya where traditions are still closely adhered to. In this regard it would have been interesting to find out about any visits to traditional healers as recent work in Kenya (Dhadphale, 1984, unpublished thesis) has shown that a significant number of psychiatric patients visit traditional healers as compared with those with physical disorders.

Anorexia Nervosa and Dysmorphobia

A Case Study

Anorexia nervosa is frequently associated with neurotic traits and symptoms. The symptomatology and history of a housebound 20-year-old woman with anorexia nervosa and dysmorphobia are described. The role of the family in maintaining the problems, use of external cues to control behaviour, overvalued somatic ideas and the definition of dysmorphobia are discussed.

Anorexia nervosa frequently occurs alongside a variety of neurotic symptoms and traits. These include neuroticism, introversion (Smart *et al*, 1976; Hsu & Crisp, 1980), depression (Morgan & Russell, 1975; Eckert *et al*, 1982) and obsessiveness (Morgan & Russell, 1975; Smart *et al*, 1976; Gomez & Daly, 1980). Following recovery of weight and menstruation these neurotic symptoms and social difficulties frequently remain. (Stonehill & Crisp, 1977; Hsu & Crisp, 1980). On average, anorexics also overestimate their bodysize compared to both normal and neurotic controls (Slade, 1985). Preoccupation with body image and food may become an overvalued idea (Thomas, 1984) and has been considered delusional by some (Bruch, 1974).

This paper gives details of the symptomatology and history an unusual case of anorexia nervosa and dysmorphobia.

Case study

A 21-year-old woman was re-referred to a university-based clinical psychology department following an overdose of

50 paracetamol tablets at 2 a.m., 1 week previously. Assessment was carried out during three domiciliary visits. The patient's pattern of eating, as assessed by 1 week of self-recording was highly abnormal. She claimed to eat an average of 122 calories (range 79-148) per day. Food was restricted to grapes, melon, apple, tea with skimmed milk and unsweetened orange juice. Most eating occurred between midday and 7 pm. She reported that she did not induce vomiting. She did not use laxatives as they were not available to her, although in the past she had used them. Her height was 5'7" and she weighed approximately 8 stone (51.3 kg).

She reported being highly pre-occupied with her physical appearance. Her aim was not to reach any particular target weight, but rather to attain a slim appearance. She considered herself to be generally too "broad". Using a Body Satisfaction Scale (Slade, 1985b) she rated 16 body parts as follows: *Very Satisfied*—none; *Moderately Satisfied*—eyes, ears; *Slightly Satisfied*—none; *Undecided*—head, nose, mouth, chest, hands; *Slightly Unsatisfied*—face, jaw, shoulder arms; *Moderately Unsatisfied*—teeth, legs, feet; *Very Satisfied*—tummy. In order to gain a better body shape, she said that she carried

out exercises for up to 1½ hours per day to 'tone-up' her muscles. She typically dressed in a skimpy nightie, underwear and housecoat and would not wear daytime clothes because she felt she looked 'broad' in them. She reported that when talking to anyone she was constantly worried about what they thought of her appearance. When people reassured her she believed that they were first trying to be kind.

She reported that she did not leave the house because of the way she looked, extreme embarrassment, and fear of comments from other people on her appearance. She had remained almost completely house-bound for over 2½ years and had left the house less than 10 times during this period. These were almost all hospital visits. Consequently she had developed a daily pattern of life within the home doing housework and reading and making notes extensively about anorexia and bulimia from books and television programmes. Secondary gains were apparent from remaining at home. These included friends (and professionals) visiting her at home, avoidance of work and anxiety-provoking social situations, and a lot of attention from family, neighbours and professionals concerning her condition. In particular, her mother was the major vehicle in her transactions with the outside world.

She also reported being highly socially anxious due to her preoccupations with what other people thought of her appearance. In addition, she was socially unskilled. Her eye contact was brief and infrequent; she often blushed, and laughed nervously and inappropriately; her posture was orientated away from the speaker, and she frequently placed her hand over her mouth and talked excessively about her appearance. Her dress was inappropriate and paradoxically drew attention to those bodily features which most embarrassed her.

There was no evidence of formal thought disorder, systematised delusions, hallucinations or a depressive disorder. Diagnosis of both anorexia nervosa and dysmorphophobia could be substantiated.

History

The patient was born by Caesarian section, weight 7 lb (3.2 kg). She had been referred to a psychiatrist during childhood for sleeping difficulties but her mother had been told that she was simply a bright, active child and there was no cause for concern. During attendance at infant school she was reportedly a fussy eater. At junior school the family reported that she did well and they were proud of her. However, she reported being self-conscious at times and recalled having been teased by her father and two brothers for 'having legs like tree trunks'. Menarche occurred unremarkably at 12 years of age.

All the family explicitly dated the onset of the problem to a school nurse remarking that she was overweight (10½ stone/66.8 kgs) following a routine health check at the age of 12 and advising that she should lose weight. She lost a few pounds but was told by her GP that this was not enough (10 stone 2 lbs/64.5 kgs). She then starved herself for 6 weeks getting down to 9 stone (57.3 kg) eating only occasionally rye bread and apple. When she was 14 years old she starved herself during the summer holiday and lost

weight dramatically. At around this time her paternal grandmother died and she was upset for quite a few days afterwards. When she was 16 years old her GP had noted possible early anorexia nervosa. At this time her elder brother suffered a single schizophrenic attack. This followed his being teased at school about his curly hair whereupon he became preoccupied with this. (He was admitted to hospital, made a good recovery and has had no relapses in 5 years since.) During the same year she sat her mock and CSE/GCE exams (6 CSEs, 1 'O' level) and under-achieved. She recalled that she was unable to concentrate and revise because of continual thoughts of food and her appearance.

After school she attended a college to study office work but only stayed for 10 weeks. She left because she thought people were laughing at her. Following this she did not leave the home once in 8 months. By this time she weighed 8 stone (53.6 lbs) and the GP referred to a psychiatrist following her mothers concern at laxative abuse. However, she refused to attend a day hospital and take medication. She was referred to a clinical psychologist but attended only one appointment. Over the next 2 years she was referred three times and again refused family therapy, psychotherapy and behaviour therapy within two or three appointments of each re-referral.

Discussion

Anorexics have been shown to depend on external cues more than control subjects in relation to food regulation (Crisp & Kalvcy, 1974; Russell *et al*, 1975; Garfinkel *et al*, 1978). Despite this finding in several independent studies involving different paradigms, anorexics do not have a more external locus of control than normal or thin patient controls (Garner *et al*, 1976). This suggests that dependence on external cues to regulate behaviour is restricted to food regulation and perception of body image rather than a general cognitive style. In the present case the patient frequently sought reassurance from others concerning her appearance and was highly preoccupied, especially in social situations, with what others might think of her appearance. Her dysmorphophobia can be seen as developing from her extraordinary reliance on external feedback concerning her physical appearance. The term 'dysmorphophobia' has been used in several distinct ways. It can refer to a non-specific personality disorder in patients seeking cosmetic surgery without physical cause (Crisp, 1981) and quite distinctly as a social phobia (Marks, 1980). In our case the term refers to a social phobia as evidence of high anxiety in social situations, avoidance of these situations, fear of criticism and adverse comments about physical appearance. Such social anxiety and commonly associated traits of neuroticism and introversion are relatively common in anorexia, both during periods

of low weight and following restoration of normal weight and menstruation (Hsu & Crisp, 1980; Smart *et al*, 1976) although a true phobia leaving the patient housebound is relatively rare.

The role of family members in the maintenance of these problems is not clear, although some speculations can be made. Firstly, a number of secondary gains were apparent both from her mother who acted as a median with the world on her behalf; her younger brother also arranged friends to visit her. The importance of secondary gains is highlighted by the obvious untruth in at least one of the patient's three claims of extremely low food intake, stable weight and long periods of exercise. Her GP confirmed that her weight had been stable for many months. Both the patient and the family appeared to subscribe to a 'romantic' view of anorexia nervosa: references to well-known anorexics were often made. Loss of high academic potential was made both by the patient and the mother and anorexia was the explicit reason given for academic underachievement. She appeared to be of average academic ability. Her brother's single schizophrenic attack may be of relevance; this was precipitated by bullying at school and was preceded by pre-occupation with physical appearance. He may have acted as a model, both specifically in terms of the content of her overvalued somatic ideas, but also

generally by legitimising, within the family, avoidance of school and academic situations through bodily preoccupation.

Organic Factors in Catatonia

A retrospective case-control study was performed using the records of 59 catatonics, 59 non-catatonic schizophrenics, 59 manics, 59 depressives and 59 surgical controls. The findings suggest that prior brain injury and physical illness at onset of psychosis are much more common in subjects with catatonia. While these findings do not account for all cases of catatonia, they may indicate an aetiology for some phenotypic cases of catatonia.

Catatonia is a clinical syndrome characterised by symptoms of mutism, psychosis, bizarre motor activity and either agitated excitement or stupor. This syndrome is generally associated with the diagnosis of schizophrenia; however, it has been noted in non-schizophrenic individuals and has been said to be a non-specific syndrome (Abrams & Taylor, 1976). Catatonia is an interesting condition because the prevalence of this disorder is felt to have decreased over time (APA, 1980).

It is possible that the reduction in the occurrence of catatonia reflects the fact that more effective treatments are now available in psychiatry and that these treatments are arresting the progression of common psychiatric disorders before they develop into a catatonic state. There are problems with this assumption. Firstly, it assumes that a common psychiatric illness must necessarily be a precursor to catatonia; this has never been proven by scientific studies and has never been strongly indicated in the clinical literature. Secondly, no intervention studies have been performed which, while evaluating the efficacy of psychiatric treatment for the larger diagnostic categories, have ever specifically evaluated the association of these treatments with catatonia as an outcome.

Since the clinical literature suggests that the frequency of catatonia appear to be decreasing with time, it is possible that the syndrome of catatonia may arise from some type of environmental exposure which has changed over time. The relative decrease in the frequency of catatonia may then reflect some type of cohort effect. Similar events have happened in the past; for example, the encephalitis epidemics of the early twentieth century resulted in a cohort of individuals with Parkinson's disease. Similarly, an exposure to a now uncommon illness may possibly have predisposed people to catatonia. Both brain injury (Gelenberg, 1976) and infection (Raskin & Frank, 1974) have been associated with the occurrence of catatonia in the past, suggesting that such exposures may be risk factors for this syndrome.

This study was conducted in order to evaluate the association of specific environmental exposures to the outcome of catatonia later in life. The specific exposures which were selected as possible precursors to catatonia were possible childhood brain injury and history of encephalitis-like symptoms shortly before the onset of psychiatric symptoms.

Method

A case-control design was used to examine prior noxious exposures among catatonic subjects and controls. Since catatonia is no longer a frequent occurrence, it was decided

that a retrospective examination of catatonic individuals would be performed using the records of our Psychiatric Hospital from patients who were admitted during the decades when catatonia was more common (1930-1945). In this way a reasonable number of subjects could be obtained. We had access to a large number of records of individuals whose psychiatric histories were very clear. Mental state examinations in these records were detailed and often 15 pages long, containing transcribed discussion with patients and their families. These patients were re-diagnosed using operational criteria (Feighner *et al*, 1972). Medical histories were also very clear and extensive. Patients with the syndrome of catatonia were randomly selected from these records. Since catatonia is so severe a condition that a period in hospital is required, we did not feel that a large selection bias was introduced by using a university hospital population for their selection. Our criteria for inclusion into the group of catatonic cases were: (1) stupor or mutism; (2) negativistic or oppositional behaviour; (3) rigid motor activity; (4) uncoordinated purposeless excitement; (5) bizarre posturing. Cases had to meet at least two of these criteria to be considered catatonic. These criteria are generally accepted as characterising the syndrome of catatonia and conform to the description of the catatonic subgroup of schizophrenia as described by the *Diagnostic and Statistical Manual of Mental Disorders (Third Edition)* of the American Psychiatric Association (APA, 1980). Using these criteria, 59 catatonic subjects were obtained of whom 57 were stuporous.

Since catatonia is generally a disorder of the young (Gjessing, 1938) and since exposure variables may differ between sexes, the catatonic subjects were matched on the variables of sex and age to control for confounding. Fifty-nine schizophrenics, 59 manics, and 59 depressed patients were selected for comparison with our group of catatonics. These psychiatric control patients were also admitted between 1930 and 1945. These patients were re-diagnosed using operational criteria (Feighner *et al*, 1972). An additional 59 sex- and age-matched surgical inpatients were also selected from the years 1931 to 1945 for comparison to the catatonic population. The two categories of exposure which were examined were: (1) possible brain injury; (2) symptoms of severe physical distress at onset of psychosis.

The criteria for admission to the first category required that a patient have a previous history of head injury so severe that it required medical attention or a history of encephalitis or a history of seizures or was a forceps delivery. The criteria for admission to the second required that patients have a history of vomiting, diarrhoea, or severe headache with severe neck stiffness or high fever immediately prior to the onset of psychiatric symptoms.

It was assumed that if there was an association between these exposures and catatonia then the catatonic group would have a higher frequency of these problems than would their counterparts in the other samples. Statistical analysis of the data was carried out by using the χ^2 test.

Results

For the first category (possible brain injury), significant differences were found in the following categories:

(1) catatonics vs manics, $P < 0.05$ (23 compared to 11); (2) catatonics vs depressed, $P < 0.01$ (23 compared to 7); (3) catatonics versus surgical controls, $P < 0.001$ (23 compared to 2). No significant difference was found in the frequency of possible brain injury as defined by our criteria between catatonics and schizophrenics (23 compared to 18).

Concerning the outcome of category 2 (physical illness at onset), the significant differences were as follows: (1) catatonics vs manics, $P < 0.05$ (18 compared to 7); (2) catatonics vs depressed, $P < 0.001$ (18 compared to 2); (3) catatonics versus schizophrenics, $P < 0.001$ (18 compared to 3). Comparison with surgical controls was not applicable in this category since they did not have an onset of psychiatric symptoms with which to compare.

Discussion

The analysis of these data was consistent with previous anecdotal findings that the onset of catatonia is frequently associated with concurrent physical distress (Gjessing, 1938). The higher frequency of possible brain injury among catatonics as compared with other (non-schizophrenic) psychiatric illnesses and controls suggests an association between psychosis (specifically catatonia) and brain dysfunction.

Although an association may have been demonstrated between the two described categories and the occurrence of catatonia, more definitive statements would not be appropriate at this time. We felt that the generally high quality of these records minimised the possibility of information bias. We attempted to use objective statements from the records in order to minimise problems with this category. It was felt

that encephalitis and seizures would generally indicate brain insult and that any head trauma severe enough to require medical attention would be very likely to also indicate this type of injury. Similarly, in the second category, stress was put on objective signs of illness in an attempt to exclude somatic delusions. By matching for age, we controlled for the possibility that variation in use of forceps delivery, over the years, would systematically isolate a diagnostic group in an artificial way.

The findings of this study suggest that there is an association between childhood brain injury and the syndrome of catatonia. This may mean that the changing prevalence of catatonia is reflective of the general improvement in health status of children over the last 50 years rather than the introduction of specific psychiatric therapies. We encourage further research in this area and hope that attempts will be made to replicate this type of study.

Suicide Among Schizophrenics:

A Comparison of Attempters and Completed Suicides

Schizophrenics who completed suicide were compared with those who made suicide attempts, on the basis of blind ratings of previous hospital records and follow-up

interviews with treating clinicians. Results indicated that the two groups were relatively distinct. Suicides tended to live alone and to feel depressed, hopeless, worthless, and suicidal. Attempters, on the other hand, lived with their families or others and were less likely to manifest several features of depression during a period in hospital. In evaluating suicide potential among schizophrenics, living situation and mental state changes indicating depression, suicidal intent, worthlessness, and hopelessness are more important than a history of suicidal behaviour.

Suicide is a frequent complication of schizophrenia (Miles, 1977), yet clinicians evaluating these patients for suicide potential face a difficult task. The empirical literature emphasises the importance of previous suicidal behaviour (Warnes, 1968; Breier & Astrachan, 1984), particularly multiple attempts (Cohen *et al.*, 1964; Shaffer *et al.*, 1974). Suicide attempts are, however, so frequent among young schizophrenic patients (Niskanen *et al.*, 1973; Planansky & Johnston, 1973) that other risk factors may be more discriminating. As is the case with other diagnostic groups, suicides and attempters probably represent different but overlapping populations (Stengel, 1962). The purpose of this study is to compare schizophrenics who complete suicide with those who make attempts.

In previous work, we identified the characteristics of schizophrenics who complete suicide through an extensive literature review (Drake *et al.*, 1985) and two empirical studies (Drake *et al.*, 1984; Drake & Cotton, 1986). In this study, we compare attempters with completed suicides on the basis of a blind examination of data from prior periods in hospital and follow-up interviews with treating clinicians.

Method

Fifteen schizophrenic patients who had undergone periods in hospital, in an urban, public mental health system between 1976 and 1980 subsequently committed suicide. A comparison group of 89 other schizophrenics, who had undergone periods in hospital, in the same treatment system during the same time period was followed up 3–7 years after index admission. Of these patients, 19 had made suicide attempts, defined as any intentionally self-inflicted injury, during the follow-up period. All 19 attempts were medically non-serious. Using a semistructured interview, treating clinicians were questioned regarding the circumstances of all suicides and attempts. They were asked to identify any changes in behaviour, mental state, family, or other relationships that preceded the suicide or attempt. All patients met DSM-III criteria for schizophrenia according to blind records review by two psychiatrists.

Patients' hospital records were abstracted to exclude any reference to subsequent suicidal behaviour and were rated independently by two research assistants according to risk factors from the literature and depressive symptoms from DSM-III. As described previously (Drake *et al.*, 1984; Drake & Cotton, 1986), these ratings were made blindly and

reliably. The results presented here are based entirely on the blind ratings of previous hospital records but in the discussion section, we use information from the non-blind follow-up interviews to generate possible explanatory hypotheses.

Results

A partial list of the 50 variables is presented in Table 1. Complete lists appear elsewhere (Drake *et al.*, 1984; Drake & Cotton, 1986). Because of the small sample size, only large differences between suicides and attempters are statistically significant. Therefore, the large number of significant variables (over 20%) suggests that there are important differences between schizophrenics who kill themselves and those who make attempts. Current follow-up of the attempters, now 5–9 years after index admission, has revealed no further suicides and supports the view that attempters are a relatively distinct group.

The two groups were largely similar in terms of socio-demographic characteristics, history of illness, and background variables. Although the suicides were, on average, 7 years older than attempters, this difference was not

TABLE I
A comparison of schizophrenic patients who completed suicide with schizophrenic patients who attempted suicide

Characteristics	Suicides (n = 15)	Attempters (n = 19)	Sig. level ¹
Age (years)	31.7	24.8	NS
Sex (male)	60%	47%	NS
Previous suicide attempt	73%	47%	NS
Three or more attempts	40%	21%	NS
Explicit suicide threat	67%	16%	<0.01
Lives with family of origin	27%	63%	<0.05
Lives alone	60%	11%	<0.01
Depressed mood	80%	52%	<0.05
Feels inadequate	80%	42%	<0.05
Hopelessness	67%	26%	<0.05
Worthlessness	53%	21%	<0.05
Suicidal ideation	87%	37%	<0.01
Fears of mental disintegration	33%	5%	0.05
High self-expectations	47%	16%	0.06
Improved at discharge	67%	32%	<0.05

1. Significance levels refer to *t* tests or χ^2 tests

statistically significant. In terms of suicide history, only a history of explicit suicide threats differentiated the two groups statistically. Other possible predisposing factors, such as a history of violence or substance abuse, failed to separate the two groups. Behaviour during stays in hospital, such as being impulsive, demanding and agitated, also failed to discriminate, perhaps because of the time-lag between the period in hospital and suicidal behaviour for most patients.

Living situation and mental state examination revealed several important differences between attempters and suicides. Attempters were more likely to be living with their families of origin. Suicides, on the other hand, tended to live alone. On mental state examination, the suicides reported feeling depressed, inadequate, hopeless, worthless, and suicidal. They also expressed higher performance expectations and fears of further mental disintegration. In addition, suicides were more likely to be 'improved' at discharge.

Discussion

Our results indicate that schizophrenics who kill themselves are more depressed, suicidal, and isolated than those who make attempts. Consistent with findings by Roy *et al* (1984), many of the attempters were depressed during their period in hospital. Those who completed suicide were, however, even more likely to be depressed and were especially prone to manifest the psychological features of depression, such as hopelessness. They were frequently 'improved' at discharge but returned to more isolated living situations.

To explain these findings, we offer several hypotheses, some of which are based on our non-blind follow-up interviews. Schizophrenics who kill themselves may be predisposed to depression and isolation by a prevailing sense of aloneness (Buie & Maltzberger, 1983). Because they are more hopeless about their futures with chronic mental illness and fear continued mental disintegration, they may kill themselves specifically to avoid this fate (Baechler, 1979). Perhaps they are predisposed to despair and self-destruction because of high premorbid achievement and persistent self-expectations that are no longer realistic (Drake *et al*, 1984). Although improved at discharge, follow-up interviews indicated that these patients lapsed into further hopelessness and depression following discharge. Suicide usually occurred in the context of interpersonal isolation. Similar to findings by Breier & Astrachan (1984), our follow-up interviews revealed that many of the suicides had experienced some loss of familial support within weeks of killing themselves (Cotton *et al*, 1985). Perhaps unwanted separation from family was a crucial stress for some of these patients. Alternatively, as suggested by

Virkkunen (1976), they may have withdrawn from family as well as others as a manifestation of their extreme hopelessness.

While completed suicides present a picture of overwhelming depression, withdrawal, and despair, suicide attempters appear to be a more heterogeneous group. Consistent with findings by Planansky & Johnston (1973), our follow-up interviews revealed a variety of situations, clinical states, and apparent motives among attempters. According to treating clinicians, these patients were often agitated or psychotic rather than depressed immediately prior to the attempt. Psychosis, lack of awareness, or lower self-expectations may have protected them from developing despair over their illness and future. The follow-up interviews also indicated that attempts frequently occurred in the context of interpersonal conflict, such as a fight with family or housemates, rather than isolation. It appeared to clinicians that some patients were trying to manipulate others, consolidate support, or gain entrance to the hospital. In addition, some of the more impulsive attempts were associated with dysphoric side-effects of medication such as akathisia (Drake & Ehrlich, 1985).

Our findings have several implications for clinicians evaluating suicide potential in schizophrenic patients. Some young schizophrenic patients, particularly when they have separated from their families of origin, will develop depression, worthlessness, hopelessness, fears of further disintegration, suicidal ideation, and social isolation. This profile is a more dangerous indicator of suicide risk than a history of suicidal behaviour or a current suicide attempt. We suggest that these high-risk patients be monitored carefully and considered for more intensive interventions, such as a period in hospital, day treatment, family therapy, and structured, group-living situations.

Trazodone-induced Mania

Two bipolar depressed patients and one unipolar depressed patient developed manic symptoms after receiving trazodone. The symptoms resolved when the treatment was discontinued or reduced. We believe the two bipolar patients are the first cases of this reaction reported in the literature.

Trazodone, a triazolopyridine derivative, is a novel antidepressant which has been studied thoroughly in the last years. More than 400 clinical studies, including 20 000 patients, have been performed on trazodone (Agnoli *et al*, 1984). Clinical trials have shown that trazodone is as effective as the tricyclic antidepressants in the treatment of depressed patients (Fabre *et al*, 1979; Kellams *et al*, 1979). Trazodone does not bind to muscarinic cholinergic receptors *in vitro* (Taylor, 1981) and has minimal anticholinergic and cardiovascular side-effects (Gershon & Newton, 1980; Cassano *et al*, 1982). Therefore, it is an attractive choice in depressed geriatric patients and in patients suffering from angina, prostatism, constipation and glaucoma (Gershon, 1984).

Roy-Byrne *et al* (1984) in their article on approaches to the evaluation and treatment of rapid-cycling affective illness, mentioned that trazodone has not yet been reported to induce mania.

In our review of the literature we found only two case reports of trazodone-induced mania (Warren & Bick, 1984) and one report of psychosis following trazodone administration (Kraft, 1983). All three patients had unipolar depression.

In this report we describe three cases of trazodone-induced mania. Two of the patients are bipolar affective patients. To the best of our knowledge this is the first report of such reaction in bipolar patients.

Case 1

Mr P, an 82-year-old widowed male, met DSM-III criteria for mixed bipolar affective disorder: for the last 22 years he has suffered from manic and depressive episodes, each lasting 3–4 months. Since the death of his wife, 15 years ago, he was admitted several times to our hospital for short periods. In between these periods in hospital he enjoyed full remissions lasting up to 3 years. Mr P was readmitted due to a relapse into a depressed state. The examination

on his admission revealed depressed mood and affect, psychomotor retardation, weight loss, and lack of interest in life: "I had better been dead".

We started treatment with maprotiline, a drug which he had received intermittently for the last 5 years, but we discontinued it after 10 days since it caused confusion. We started treatment with trazodone, 50 mg/day, 7 days later and increased the dose to 100 mg/day the following week. After 2 weeks of treatment with trazodone Mr P regained his appetite, showed interest in everyday life of the hospital, and was given permission to visit his apartment. On the following day his mood became elevated, he worked day and night, cleaning his apartment, spent money without limits, and did not want to return to the hospital. When he finally returned, he showed pressure of speech, fanciful ideas, restlessness, and reported a marked reduction of sleep. Trazodone was discontinued and treatment with haloperidol was started. One week later Mr P's condition improved, and his mood and behaviour stabilised.

Case 2

Mrs N, a 35-year-old single woman, met DSM-III criteria for mixed bipolar affective disorder. For the last 15 years she had suffered from nine episodes of either depressed or manic states, each lasting approximately 5 months; in between she enjoyed full remissions. She was readmitted in a depressive episode with marked psychomotor retardation. Mental state examination on admission revealed depressed mood, slow speech, and rumination of inadequacy feelings. We started treatment with chlorimipramine, up to 250 mg/day, for 6 weeks, followed by imipramine, up to 300 mg/day, for another 6 weeks, with no improvement. We started treatment with trazodone 5 days after imipramine discontinuation and increased it in 4 days up to 300 mg/day. She demonstrated psychomotor agitation 5 days after the beginning of this treatment, hypereuphoria accompanied by irritability, and insomnia, resembling her behaviour during previous manic episodes. She even became violent, attacked one of the nurses and tore her uniform. Trazodone was discontinued and treatment with haloperidol was started. Within 4 weeks Mrs N returned to her premorbid state and was discharged.

Case 3

Mrs S an 84-year-old married woman, met DSM-III criteria for recurrent major depression: during the last 20 years she had several depressive episodes, each lasting 6-8 months, and did not have manic episodes. She was readmitted after a full remission of 3 years, 1 month after she underwent a nephrectomy for a malignant renal tumor. At that time her mood became dysphoric and she demonstrated loss of energy, reduced concentration, insomnia, and poor appetite. On admission her mood and affect were both depressed, and she revealed suicidal intentions. Her laboratory examinations including renal function tests and a whole blood count were normal. We started treatment with trazodone, and increased the dose up to 300 mg/day. After 8 weeks of treatment Mrs S's state improved: she slept

well, her appetite was better and she was more active. However, 2 weeks later she became very restless, talkative and easily distractible, showed inflated self-importance and tended to react angrily towards the staff and her visitors. She was running around the ward cursing the nurses and her family, and slept only a few hours (3-4) each night. This change lasted for a week. The dose of trazodone was reduced to 150 mg/day with a marked improvement, and follow up during the next 4 months found the patient in a good stable condition.

Discussion

The association between trazodone administration and the development of a manic state is supported by the following observations:

1. The symptoms appeared a short time after the beginning of the treatment in patients 1 and 2 (the bipolar patients). Patient 3, in whom the symptoms appeared after 10 weeks, had suffered only unipolar depression for 20 years.
2. The symptoms disappeared with the discontinuation (patients 1 and 2) or the reduction (patient 3) of trazodone.
3. The manic episode in the bipolar patients was different from the previous manic states: it lasted only weeks and resolved quickly following drug discontinuation and treatment with haloperidol.
4. The patients received trazodone without any other antidepressant drug. There was a 'wash-out' period of 5-7 days in the bipolar patients, and patient 3 received trazodone as the first antidepressant drug in this admission.

We assume that trazodone induced the manic reaction in the three patients described.

A Case of Resistant Schizophrenia

In an era when it is generally believed that the acute symptoms of schizophrenia can be controlled pharmacologically, the case of a young man who has remained almost continuously floridly psychotic for 13 years, despite treatment, is disquieting. Conventional psychiatric treatment appears to be rendered impotent. It is in this context that it may be of interest to report a summary of the proceedings of a Special Problems Conference held at the Institute of Psychiatry on 18 February 1985 to discuss such a case.

Case report

Mr A is a 31-year-old single Caucasian first seen in 1971 with the diagnosis of schizoid personality disorder. In 1974, he was admitted to hospital for the first time, diagnosed as a paranoid schizophrenic. He had florid symptoms of schizophrenia including thought disorder with frequent neologisms, thought echo and broadcasting, delusional mood and persecutory delusions. Initially he showed some minimal response to phenothiazines but he remained an inpatient for nearly all of the next 3 years with only two short periods—of 21 and 10 days—when free of psychosis. Although virtually continually and floridly psychotic, there was a marked fluctuation from week to week in the degree to which the symptoms were evident. In addition, a consistent exacerbation of psychosis was noted with social stress. Treatment included a wide variety of antipsychotics as well as high-dose propranolol. He was finally transferred to the hostel ward in the Maudsley Hospital in 1977 and later to a local hostel in 1982. Over this period he became a little more sociable and less overtly psychotic, although some paranoid features remained. Drug treatment at this stage had been considerably reduced to haloperidol 15 mg daily. He voluntarily stopped all medication in December

1981 and 1 month later was noted to be increasingly psychotic and to show evidence of tardive dyskinesia. He was out of contact with hospital care until readmitted in an actively psychotic state in January 1983. He has remained an inpatient since, with no remission at all in his florid schizophrenia despite a range of antipsychotic medication, at times in high doses. He has become much more distressed on occasions and attempted to climb from a high level window. He was treated with a course of six ECT for a possible affective component to his disorder but with little benefit. Current medication is fluphenazine decanoate 100 mg weekly, chlorpromazine 200 mg four times daily and procyclidine 5-10 mg infrequently.

Background history

Mr A comes from a working-class Irish family and is the younger of two siblings. His father disliked social contact and left home when the patient was 18 months old, with no subsequent contact. Mr A's mother remarried a man considerably younger than herself when the patient was aged 14 and 1 year later she had the first of several myocardial infarctions. A maternal aunt died of Parkinson's disease, but no family history of psychiatric illness is known. The

family were very close-knit, living with the maternal grandmother until she died. He refuses any contact with his family now, asserting that "they are all replicas".

The patient was born by a normal delivery after maternal pre-eclampsia and induced at 36 weeks. His birth weight was only 2.04 kg (4.5 lb) and there were severe respiratory difficulties, requiring artificial ventilation. Information on the neonatal course is limited but mother was told that there was "no hope". Developmental milestones, nevertheless, were normal. He was an average scholar, but noticeably quiet and withdrawn, with few friends. Other than a few, short-term casual jobs after leaving school, he has been unemployed. He has no history of alcohol or drug abuse.

Present condition

Mental state

Mr A's mental state has not essentially changed over the last few years and shows a full complement of schizophrenic symptoms. He is often seen, a little dishevelled, in heavy army clothes, lying on the floor. He interacts little with other patients but on occasions he may participate surprisingly well in groups, showing considerable warmth. His expression is usually blank but he may be worried or suspicious; he may roll his eyes up voluntarily when particularly distressed. At these times his speech is often slurred. Usually, he will answer promptly, but rapidly goes off the subject to reveal marked thought disorder, one delusion following the other with no logical sequence and with frequent neologisms. He is apprehensive and worried, often about his physical health, but not thought to be currently depressed. On occasions he is much more distressed and seems tormented by his persecutory or hypochondriacal thoughts. Some ideas of reference and passivity experiences are present as well as thought echo, insertion and broadcasting. Both third person auditory hallucinations and somatic hallucinations feature. There is no cognitive impairment. Insight is generally minimal.

Physical examination

This did not reveal any neurological abnormalities.

Investigations

Investigations have all been normal including repeated CT scans, EEG and urinary drug screens. Serial psychometric testing shows no evidence of deterioration in the last 11 years: full-scale IQ has been consistently in the range of 85-95. Prolactin level is 939 mu/litre and chlorpromazine levels are: pre-dose 0.65 mg/litre, post-dose 0.75 mg/litre.

Conference

The conference was asked to consider two broad questions. What relevance do current biochemical theories of schizophrenia have in the light of the evidence of dopamine blockade in our patient? Secondly, how best should he be managed both in terms of situation and medication? Is his present environment too stressful for him? Is there any

justification for continuing medication at all now in a man who appears to be truly neuroleptic resistant? Alternatively, could any other drug be useful for this man?

Professor Griffith Edwards, chairing, introduced the discussion in an optimistic tone by commenting that currently we were making a case conference occasion of a schizophrenic who did not get better whereas even 30 years ago it would have been more probable that we should have been meeting to discuss with surprise a schizophrenic who had actually recovered.

Professor Malcolm Lader agreed but observed that this patient was different from most cases of refractory schizophrenia. Chronic schizophrenia is usually of the socially withdrawn type with a defect state and our patient was unusual in this his symptoms were so unrelentingly acute.

Author's note: Mr A is clearly an unusual case and poses considerable management difficulties. The literature, however, is not very helpful. Even the number of patients with persistent positive symptoms of schizophrenia is uncertain since many long-term follow-up studies (Sherman *et al*, 1964; Bleuler, 1972; Huber *et al*, 1975; Gelder & Kolakowska, 1979; Ciompi, 1980) do not specifically mention this group, presumably subsuming such patients into the category of 'chronic schizophrenic'. Earlier follow-up studies distinguished only between hospitalised and discharged patients. More recently, combined estimations using clinical, social and occupational measures have been introduced. Even so, as Bland & Orn (1978) make clear, rates of recovery in the literature are not always comparable. There is some agreement, however, that about 5-15% of schizophrenics remain continuously in hospital. The group who remain actively psychotic is probably smaller: in Huber's (1975) sample, 4.2% showed 'chronic pure psychosis'. A recent study of 77 schizophrenics by Kolakowska *et al* (1985) in Oxford suggested that at least 11 of those 20 patients with a poor outcome had been continuously ill since their first episode.

Professor Lader commented that even though the high plasma level of chlorpromazine may have been beyond the possible therapeutic range, there seemed little evidence to support the possibility of a toxic psychosis in our patient.

Dr John Crammer was particularly interested to pursue the possibility of depression at times of increased distress in this man. He emphasised that schizophrenics may well suffer from secondary affective illnesses, noting that the discovery of imipramine as an antidepressant had been made when treating schizophrenia and a mood change had been observed.

Author's note: Having excluded these possibilities, even then not all those schizophrenics with a poor outcome are necessarily neuroleptic resistant: both the nature of the schizophrenic illness and drug-related factors are important determinants. Gelder & Kolakowska (1979) have proposed a model in which they classify schizophrenic patients into four groups: remitters, responders, inadequately treated and neuroleptic resistant. The groups are distinguished on the basis of both clinical and pharmacological criteria. Thus, clinical improvements may occur because of either spontaneous remission or the effect of medication. Poor outcome, on the other hand, may result from suboptimal pharmacological effects of medication or because of true neuroleptic resistance. Clarification of this sort aids both clinical management and research.

Patients may be inadequately treated for a variety of reasons including non-compliance and individual differences in drug metabolism which alter dose requirements. Over 100-fold variations in chlorpromazine blood levels between different patients on the same dose have been reported (Curry *et al.*, 1970). There may also be extensive metabolism of an oral dose of chlorpromazine in the gut wall, accounting for the improved response that may be seen with a parenteral antipsychotic. The usefulness of phenothiazine levels has been debated at length: chlorpromazine, for example, has at least 168 metabolites, of varying potency. In addition, whilst there seems to be a relationship between plasma chlorpromazine level and plasma prolactin level, the association between chlorpromazine level and clinical response is less certain. Whether or not a 'therapeutic window' exists for neuroleptic treatment is similarly not yet established.

Professor Lader nevertheless suggested that medication could be withdrawn to see if any response occurred perhaps corresponding to such a window.

Dr John Cutting pointed out that not only had neuroleptics been disappointing in this man, but furthermore, it was unlikely that phenothiazines would induce remission in the future in the presence of thought disorder and possible antecedent brain damage.

Author's note: Most investigators have concentrated on this question: whether those patients with an unfavourable outcome can be predicted at an early stage. It is generally accepted that the following factors are all associated with a poor prognosis: low IQ, childhood difficulties, poor premorbid adjustment, presentation before 15 years, low social class, single status, insidious onset and absence of affective features. Huber (1975) found that those with somatic and auditory hallucinations and with a predominance of hebephrenic symptoms had an unfavourable prognosis. According to Murray (1984), however, positive symptoms are not of much importance prognostically. Negative symptoms such as emotional blunting and withdrawal are bad signs. Although it has been suggested that response to neuroleptic medication may depend on the stage of illness (Left and Wing, 1971), in Kolakawska's study (1985), both clinical response and outcome were related to the type of illness rather than its duration.

Much interest has centred on the possible association between 'organicity' and response to neuroleptics and outcome. Weinberger (1980) originally reported that clinical response was significantly worse in patients with cerebral ventricular enlargement. This finding was confirmed by Luchins *et al.* (1984). The Oxford study did not replicate this association (Williams *et al.*, 1985) nor did it find evidence for an association between the presence of organic brain disorder (both neurological signs and cognitive impairment) and poor outcome. Cognitive impairment alone, however, was related to the severity of the residual disorder and resistance to treatment (Kolakawska *et al.*, 1985). It is of interest to note that there was no evidence of such deterioration in Mr A.

How could organic brain disorder arise? Speculation has centred mainly for a putative role for perinatal trauma.

Dr Robin Murray was of the firm opinion that this case of schizophrenia was one in which the aetiology was obvious, pointing out the reported perinatal problems and

lack of a family history of psychiatric illness. Perinatal difficulties associated with later schizophrenia are most frequently in those without a family history of psychosis. Indeed, it has been suggested that there are two predominant aetiologies in schizophrenia: a genetic predisposition and environmental trauma to the brain. Perinatal trauma, Dr Murray maintained, was then clearly responsible for the illness in this man and it was only because of the insensitivity of current brain imaging techniques that the minimal brain dysfunction had not been demonstrated. He also felt that, although no studies had considered this question adequately, familial cases responded more readily to antipsychotics, perhaps implying a less fundamental role for dopaminergic abnormality than in the sporadic cases.

Author's note: That there are patients who are truly neuroleptic-resistant raises doubts about the way in which neuroleptic drugs are thought to have a therapeutic effect in more responsive patients. Indeed, it raises uncomfortable questions for the hypothesis that schizophrenia results uniquely from dopaminergic over-activity. In our patient, for example, there is convincing evidence of dopamine blockade. It seems that the assumption that schizophrenics are a homogenous group is becoming increasingly less tenable. Are neuroleptic-resistant patients dopamine independent? Have irreversible changes occurred in the central nervous system? These questions are evidently so uncomfortable that the conference was reluctant to pursue them.

Professor Lader did comment, however, on the history of Parkinson's disease in an aunt of the patient since it used to be thought that this was incompatible with schizophrenia in the same family.

Dr Stuart Checkley continued, however, that this was no longer thought to be the case. Different parts of the brain were predominantly affected; the corpus striatum in Parkinson's and probably the frontal regions in schizophrenia.

Author's note: Is there any more effective treatment for the unfortunate group of neuroleptic-resistant patients? A wide variety of treatments, including diet, acupuncture and ECT have been investigated in the past. That haemodialysis had no place in the treatment of schizophrenia was only convincingly shown as late as 1983 (Carpenter *et al.*, 1983).

The role of conventional neuroleptic in megadoses was reviewed by Aubree & Lader (1980). They conclude that a minority of psychotic patients may benefit from increased doses. This was, however, for a group of presumed fast metabolisers who were not, therefore, strictly neuroleptic-resistant, as our patient. Other antipsychotics have been relatively recently studied such as sulpiride, molindone, loxapine and clonidine. *Sulpiride* is a substituted benzamide which blocks dopamine (D_2) receptors which are independent of the enzyme adenylate cyclase. It may induce relatively few extrapyramidal side-effects and it has been claimed that the drug has both an anti-autistic and antidepressant effect. As an antipsychotic, it seems to be at least as effective as more conventional neuroleptics, but by virtue of its prolactin increasing effect, may induce galactorrhoea and amenorrhoea (Gerlach *et al.*, 1985). Both *molindone*, an indole, and *loxapine*, a dibenzoxapine derivative, have been investigated in the USA and are thought to be dopamine receptor blockers (Davies, 1976).

There is little evidence, however, that they are any more effective than standard antipsychotics although Lehmann *et al* (1981) reported three chronic, treatment-resistant patients who markedly improved on very high doses of loxapine. Transient numbness was reported in two of the three patients. *Clonidine* has received more interest in the UK. Although it may be an effective alternative to neuroleptics, its usefulness may largely be for those patients who have already responded to conventional antipsychotics but have troublesome side-effects (Freedman *et al*, 1982). Our patient would, therefore, be unlikely to benefit. *Propranolol* has been widely investigated as a treatment in schizophrenia, both on its own and as an adjunct to neuroleptic medication. Results from uncontrolled investigations are contradictory but a double-blind, placebo-controlled trial by Pugh *et al* (1983) showed propranolol used as an adjunct to have a more beneficial effect than placebo alone, although not as markedly as previously reported. The improvement was greatest after 3 months of treatment which may indicate the need for a prolonged trial in chronic patients. Our patient, however, was treated for many months with propranolol but with little effect. Propranolol is a β -adrenergic blocker but its mode of action in schizophrenia is not clear. It may possibly interact with 5HT receptors or, as more recently suggested, interact pharmacologically with neuroleptics. *Ceruletide*, an analogue of cholecystokinin, which is now known to be a central nervous system transmitter, has also been reported to be beneficial in schizophrenia in several open trials. A double-blind study involving chronic schizophrenic patients whose previous response to neuroleptics had been suboptimal found that there was no beneficial effects (Mattes *et al*, 1985).

In spite of the drawbacks of more recently introduced antipsychotics, could further medication be useful in our patient?

Professor Lader felt that it should first be ascertained whether cessation of medication had been followed by relapse or relapse was followed by cessation of medication.

Dr Checkley made the point that as attempts to block dopaminergic neurotransmission had failed to produce a therapeutic response, another line should be tried and suggested an attempt to block noradrenergic as well as dopaminergic neurotransmission. Neuroleptic drugs block α -adrenoceptors as well as dopamine receptors and amphetamines release adrenaline as well as dopamine. Hence, he went on, it was as logical to posit an over-activity of noradrenergic and dopaminergic mechanisms as it was to suggest an over-activity of dopaminergic mechanisms alone. Clonidine reduces noradrenaline activity by stimulating auto-receptors, thus reducing both noradrenaline release and firing. He felt that a trial period of clonidine was warranted in this man but acknowledged that those who had previously had a good response to neuroleptics seemed to respond better to clonidine.

Professor Lader wondered whether an amine depletor such as tetrabenazine or oxyperline could be useful if symptoms persisted in Mr A.

Dr Cutting, pessimistic of a response to antipsychotics in this patient, suggested instead that medication should be directed against specific abnormalities of the mental state such as anxiety or suicidal behaviour.

Dr Crammer remarked that in the past a schizophrenic with this degree of disturbance, unhappiness and unresponsiveness might well have had a leucotomy. One such patient under his care was continuing to do well after his operation in 1952.

Author's note: The problem, then, of the drug-treatment resistant patient remains unsolved pharmacologically. A more fruitful line of management may lie in a change of social environment. Our patient may well find his active ward environment too stressful.

Professor Lader agreed: there was, he thought, a strong argument for asylum in this man. It was, therefore, important to assess the relationship between his symptom severity and type of social pressures on him.

Dr Murray concurred, acknowledging the undoubted improvement in the quality of the lives of those schizophrenics who respond well to antipsychotic medication. He was, however, sceptical of the ability of the more resistant cases such as this to cope outside a non-hospital environment. This man had never done so and, in Dr Murray's view, it was cruel to keep attempting to place him in environments with levels of social stress that were harmful to him. He clearly required long-term care in an unthreatening asylum environment, such as he would have received 30 years ago. A combination, however, of therapeutic zeal on the part of psychiatrists and Government economies has resulted in the running down of asylums. He was encouraged that the effects of such a policy were at last becoming apparent with, for example, the publication of the recently highly critical report of a Select Committee of the House of Commons (1985).

Author's note: Manfred Bleuler was not an advocate of heavy and prolonged use of powerful antipsychotic drugs; he emphasised the importance of patients' environments and in particular the need for therapists to relate to the healthy aspects of psychotics. This conference, however, paid scant regard to a more psychotherapeutic approach. Is there any role for psychotherapy in such patients? A few studies have looked at this question but they are fraught with methodological problems (Feinsilver & Yates, 1984; Tuma & May, 1979). Whilst it would be a brave psychotherapist indeed who would take on our patient, that should not preclude striving for some empathic understanding with the psychotic schizophrenic. This was clearly illustrated by Van Putten *et al* (1976) who found that grandiosity was the most powerful discriminant between drug defaulters and compliers. The former may well prefer their delusions of grandiosity to drug-induced normality.

Professor Edwards acknowledged that the conference would have gained from hearing more of a psychotherapeutic view. He emphasised that we should be aware that the framework of the conference discussion—largely biochemical, neuropsychiatric and genetic—was a function of current thinking and within a given context. It could, therefore, change. Indeed, there were hints of such a change in the parameters of the debate with the importance attached in the conference to the milieu of the hospital and more broadly in the work of Dr Julian Leff.

Before bringing the discussion to a close, Professor Edwards was keen to consider the prospects for future research in this country. Should we concentrate our efforts

in investigating antipsychotic medication, for example, into a biological approach using animal models or use a more clinical approach?

Dr Checkley clearly indicated the advisability of large-scale empirical testing.

Professor Edwards doubted whether this country had a sufficient clinical research organisation for such a programme to take place.

Author's note: The parameters of the debate can be seen quite clearly to include more political issues also. Further research is urgently needed for neuroleptic-resistant patients such as ours. Current treatment offers little and he remains floridly psychotic and very distressed.

Acknowledgements

I should like to thank Dr A. D. Isaacs for permission to report this case.

Panic Attacks

SIR: Gelder's review of panic attacks (*Journal*, September 1986, 149, 346-352) provides opportunity for a further comment on this topic. Gelder does not conclude that hyperventilation is a cause of panic attacks, but he does lean to the view that lowering of arterial CO₂ may be a contributory factor. That hyperventilation is the principle cause is fast becoming a fixed belief, and some arguments in support of this are set forth by Hibbert (1984). Furthermore, a therapeutic technique based on the induction of the symptoms of tetany (listed in the second column of Gelder's table), and cognitive restructuring of the consequent apprehension, supposedly supports the argument that lowering of arterial CO₂ is an essential component in the development of a panic attack. Before this view becomes dogma and is taught as fact to generations of clinicians in training, the contrary evidence should be considered.

Firstly, there is the fact, recognised by Gelder, that not all patients who develop panic attacks hyperventilate. Secondly, Hibbert (1984) states that people who hyperventilate become anxious—but this is contradicted by observation and research (Bass & Gardner, 1985).

The third misleading assumption is that the tetanic symptoms of hyperventilation are the same as those experienced during a panic attack; some of the somatic symptoms, e.g., paraesthesia, may be common to the two states but the 'apprehensive feeling' of hyperventilation is of a different order to the overwhelming anxiety accompanied by fear of dying or becoming insane which is the pathognomonic feature of a panic attack. Fourthly, the relationship of CO₂ to the neuronal systems mediating the experience of anxiety is complex, but other evidence points to the conclusion that *raising*, not lowering, arterial CO₂ induces anxiety (Gorman *et al.*, 1984; Woods *et al.*, 1986). Whereas the proponents of the hyperventilation hypothesis induce anxiety by deep breathing in their therapeutic technique, others (e.g., Griez & van den Hout, 1983) use inhalations of CO₂ to induce anxiety.

The categorisation of panic disorder in DSM-III followed the observation that this form of anxiety may respond to antidepressant drugs and this implies a 'biogenic' explanation of the disorder. I have the impression that the hyperventilation theory has

gained ground among those who wish to establish an alternative 'psychogenic' explanation. Much of the problem, as is always the case in psychopathology, rests on the definition of states; the reading of many research reports and some books on the topic leads me to the conclusion that the flexible word 'panic' is used in different senses and to support different views. No doubt debate is in progress as to whether ICD-10 should follow the example of DSM-III and categorise 'panic disorder'. If so, we must all be sure what we mean. It seems to me that the debate is irrelevant: West & Dally (1959) described another form of anxiety disorder responding to antidepressants before the observations of Klein (1964) which were the impetus to the DSM-III category. Of greater importance than categorisation is the establishment of clearer clinical guidelines as to which forms of anxiety disorder may respond to pharmacotherapy and for which forms psychological therapy is the procedure of first choice.

Childhood Encopresis Extended into Adult Life

SIR: Fraser & Taylor (*Journal*, September 1986, 149, 370-371) wonder how many people have encopresis

extending into adult life. We report a small follow-up study which involved 22 teenage soilers (4 girls and 18 boys) admitted to an in-patient psychiatric adolescent unit who were followed up for 2–11 years (mean = 5 years; s.d. = 2 years) after discharge. They had been treated at High Lands Adolescent Unit, Scalebor Park Hospital, Burley-in-Wharfedale, between 1973 and 1983. Mean age on review was 19 years (s.d. = 4 years, range = 15–25 years); mean age at the time of admission was 13.5 years (s.d. = 3.7 years). All were of normal intelligence, and social class was mostly III (Registrar General's Classification). There was associated nocturnal enuresis in eight of them. Average duration of stay in hospital was 5 months (s.d. = 2 months); two were re-admitted. Twelve of them were considered to be conduct disordered, one had obsessional neurosis, one had a severe anxiety state, and one was depressed. Treatment consisted of toilet training, often with supplementary laxatives, therapy and family counselling.

Family doctors provided information on follow-up in all instances. Five former patients agreed to be interviewed, and another eight agreed to complete a review questionnaire. These 13 completed the 60-item GHQ and the Leeds Scale for Anxiety and Depression. It was found that there were three definite soilers between the ages of 17 and 23.

Case reports: (i) A 23-year-old man had been treated at the age of 16 with severe soiling and conduct disorder. Corroborative information came from both questionnaire and family doctor.

(ii) A 19 year-old man who was employed on a high rise building-site had been treated at the age of 14 years, and had subsequently been re-admitted for a recurrence of soiling. He was interviewed at follow-up and said he had a tendency to soil when out of reach of toilets.

(iii) An 18 year-old man who had been admitted at the age of 14 had been considered as conduct disordered and had nocturnal enuresis. Information in his case came from the family doctor. He was still soiling.

None of these three showed any evidence of psychiatric disorder on the GHQ or Leeds Scales.

The family doctors provided a control group selected randomly from their lists. None showed any evidence of soiling, although one 18 year-old had been treated for faecal impaction without soiling. For the 13 who completed the GHQ the mean score was 3.6 (s.d. = 1.9). One individual had a score of 11, indicating possible psychiatric disturbance. He had been treated by a psychiatrist. The mean anxiety score on the Leeds Scale for the 13 was 4 (s.d. = 2) and for depression was 2.3 (s.d. = 1.5).

We would like to thank Mrs B. Morris, who greatly assisted in the carrying out of this small project

Clopenithoxol in Aggressive Mentally Handicapped Patients

SIR: We read with interest the report by Mlele & Wiley (*Journal*, September 1986, 149, 373–376). They conclude that "clopenithoxol decanoate may be useful in reducing aggressive and disruptive behaviour in mentally handicapped adults". But has this finding any reliability? We do not know whether the effect was specific to depot clopenithoxol because "none (of the patients) had been given depot phenothiazines" (presumably meaning depot neuroleptics, because only one depot phenothiazine is available). We cannot be certain that there were beneficial effects, because the ratings of behavioural changes were crude, as the authors observe, and even more importantly, they were not carried out blind to the treatment. A control group having placebo injections would be essential.

The paper is further weakened by the absence of diagnostic criteria for the use of the medication. It is disturbing that potent medication given by injection is being advocated for non-specific behaviour disturbances, which invites accusations of the use of 'chemical strait-jackets'.

We appreciate the diagnostic problems in people with mental handicap and the difficulties in their clinical management, but we think that the administration of drugs for behavioural control, rather than for the treatment of specific diagnosable illness, needs justification. With contemporary multiprofessional interest in behaviour modification techniques and non-institutional care, doctors need to be clearer about the indications for intervention with medication, rather than advocating its use on non-specific grounds.

Cost of Community Psychiatry

SIR: Hoult (*Journal*, August 1986, 149, 137–144) is to be commended for the enthusiasm and enterprise he

has shown in developing an alternative to hospital-based psychiatry in Victoria. However, we are concerned that the figures quoted in his article may be uncritically repeated as showing that his alternative form of psychiatric care, based on heavy community involvement and boarding house care, is cheaper than conventional hospital-based psychiatry and should make hospital care redundant. The standard method of calculating such figures involves the cost of each in-patient day taken as a fraction of the total expenditure of that institution on clinical work. This figure is usually fairly large, and is therefore unlikely to be exceeded by other costs, even when these are relatively complicated such as setting up the boarding house supervision described in Hoult's paper.

Provision of community-based psychiatry, even when it is as effective as that described by Hoult, does not necessarily reduce the cost of hospital psychiatry. A full range of services is necessary to treat the most disturbed patients, a service that was necessary for even some of Hoult's intensively treated experimental group, and if such a service is to be maintained the total cost per in-patient will rise as the number of beds is reduced. Recently, following expansion of our services into the community, we were able to reduce the acute in-patient services from our inner-city sector in Nottingham (population 70 000) from 30 to 18 beds. This involved transfer to a different ward, and was expected to be accompanied by a reduction in nursing staff. However, because of the need to maintain adequate numbers of well-trained staff to deal with the smaller numbers of often disturbed patients, the number of nurses on the ward was reduced by only one. If we had used the standard cost-effectiveness calculations as described by Hoult our community-based service would appear a great deal cheaper, as there have been fewer admissions staying for a shorter time. Significant savings can only be made by running down the hospital end of the service. This would be quite inappropriate, and would lead to a two-tier system whereby all the best care was given in the community and those who failed to remain in community care would receive an inferior form of custodial care in hospital. For this reason we advocate that all community psychiatry should be closely linked with a hospital base so that such a two-tier system cannot develop. The hive system of care (Tyrer, 1985) emphasises the need for staff to work from a hospital base but to have extensive community involvement and, in the longer term, this can only be achieved by rotating staff between hospital and community activities. This has been tried in Sweden (Perris *et al*, 1985) and preliminary results are encouraging.

Despite the enthusiasm and effort of Hoult's experimental team, the fact that some patients needed to be admitted to hospital demonstrates that hospital and community psychiatry cannot exist in isolation. The future lies in integrating the essential components of both, not in abandoning one at the expense of the other.

Witchcraft and Psychotherapy

SIR: The article by Neki *et al* (*Journal*, August 1986, **149**, 145-155) is not only of relevance to mental health professionals in Africa and other areas of the Third World, but also to those working with immigrant populations in Western countries. The review confirms that beliefs in magic causation are not abandoned under 'Westernising' influences in Africa; in fact, magic beliefs and practices are often intensified under conditions of rapid socio-cultural change, with its attendant psychopathology. This was apparent twenty years ago (Jilek, 1967).

The article conveys an overall negative view of African traditional healers by using the label witch-doctor in a pejorative sense. In colonial times witch-doctor was the blanket label for all 'native' diviners, healers, medicine men, magical ritualists and herbalists. The demise of colonial rule brought a re-evaluation of non-Western therapeutic systems and a more positive assessment of traditional therapists (Jilek, 1971). Neki *et al* convey the impression that witch-doctor is more or less synonymous with sorcerer or witch. There are, however, quite distinct categories of traditional diagnosticians and therapists, with different functions and often specialisations, everywhere in Africa, including Tanzania and even in smaller tribes, as we found out in field work among the Wapogoro (Jilek & Jilek-Aall, 1967). It is regrettable that Neki *et al* fail to find any usefulness in the collaboration between Western-trained health staff and traditional practitioners, pioneered with considerable success by Lambo and his colleagues in

Nigeria (Lambo, 1964). They hint that such collaboration is "undesirable on moral grounds". This authoritative censure is made in connection with a reference to our co-operative relationship with traditional healers in a different culture area, that of the Northwest Coast Indians of North America. The therapeutic ceremonials described (Jilek & Todd, 1974) have nothing to do with witches, witchcraft or sorcery. The witch-doctors referred to in our article endeavour to assist, by means of a culture-congenial traditional psychotherapy and sociotherapy, those North American Indians who under the impact of rapid socio-cultural change are showing symptoms of anomic depression and anxiety.

While working with tribal societies in three continents, I have had the experience that friendly contacts and monitoring collaboration with traditional practitioners who have an established role in their community is more beneficial to the patient than ignoring or condemning them. Such collaboration becomes a necessity in the planning of comprehensive primary health and mental health care in a developing country with limited professional manpower resources (Jilek, 1985).

Depression in Schizophrenia

SIR: The paper by Elk *et al* (*Journal*, August 1986, 149, 228–229), looking at rates of depressive symptoms in schizophrenic patients from three "racial" groups, raises a number of issues.

One might question results based on small numbers (groups of 19, 15 and 22 patients) but, more importantly, is it methodologically valid to compare three such disparate groups without considering other variables? No information is given in the paper about patients' social circumstances or how typical they are of patient populations in the three "racial" groups. Referees and readers of the *Journal* may not know that black, coloured and white patients in South Africa by law have to be nursed in separate wards, usually separate hospitals, and that black and coloured people have extremely limited access to medical care.

A further point is that the reasons for comparing these three groups are not explained; is it because they were thought to be biologically different or were from different social backgrounds? Referees should ensure that the assumptions underlying a research project are clarified for the readership in either the introduction or the discussion.

Finally, there are many who would suggest that at the present time, papers from South Africa should not be published by British journals. It would be helpful to have some editorial comment on this issue.

Macrocytosis and Cognitive Decline in Down's Syndrome

SIR: Welfare & Hewitt (*Journal*, April 1986, 148, 482–483) suggest that in Down's syndrome cognitive decline and macrocytosis may be related. The causal relationship they suggest is unlikely. While red blood cell (RBC) membranes may age more rapidly in patients with Down's syndrome, this would lead to these RBC becoming smaller rather than larger. The macrocytosis seen in patients with accelerated ageing of RBCs due to thalassaemia or haemolysis is caused by the large size of the reticulocytes produced in response to the RBC loss (Beard, 1978).

Welfare & Hewitt state that in their Down's syndrome patients "there was no evidence of vitamin B12 or folate deficiency to account for this further increase" in RBC size. Eastham & Jancar (1983) state that Down's syndrome patients with macrocytosis were "not being treated with anticonvulsants and were not anaemic". It is well recognised that functionally significant folate deficiency in association with macrocytosis may be present in patients without megaloblastic anaemia being apparent (Botez &

Reynolds, 1979). I would suggest that macrocytosis and cognitive decline in Down's syndrome is likely to be related to undetected folate vitamin deficiency consequent on institutional nutrition, complicated by the gastrointestinal malabsorption that some Down's syndrome patients have.

Dependence on Pseudoephedrine

SIR: Sympathomimetic amines are a major ingredient in proprietary medications for the treatment of upper respiratory tract infections. We describe a patient dependent on pseudoephedrine.

Case report: The patient first presented at the age of 21, with symptoms of depression. This responded poorly to treatment, and continued for 12 years. In the eleventh year she was convicted of the theft of a medical prescription pad and for making a prescription for herself for Actifed. She subsequently admitted taking between 50 and 300 ml/day of this preparation — the recommended dosage is 30 ml/day. She said that she took it because it "gave her a lift". A year later she began to describe psychotic symptoms, which have lasted for four years. She had auditory and visual hallucinations and passivity feelings. These symptoms fluctuated and were variable in content; she showed none of the negative symptoms of schizophrenia. Although it was not possible to make a diagnosis of schizophrenia, she clearly suffered from depression, had an unstable personality, and had abused Actifed. Treatment included both oral and depot phenothiazines in addition to supportive psychotherapy, but her compliance was poor.

The present report is important because it shows that dependence and possibly psychosis can occur with over-the-counter preparations. Each 5 ml of Actifed contains 30 mg of pseudoephedrine hydrochloride and 1.25 mg of triprolidine hydrochloride. Dependence on amphetamines and other sympathomimetic drugs is well known. There is, however, only one report of dependence on pseudoephedrine (Diaz *et al*, 1979). Visual hallucinations on attempted withdrawal are described in that report. Paranoid psy-

chosis after abuse of Actifed has also been described (Leighton, 1982). The patient's fluctuating psychosis is thus in accordance with previous findings.

Admission Rates and Lithium Therapy

SIR: Dickson & Kendell (1986) recorded admissions for mania and psychotic depression in Edinburgh over the years 1970–1981 and found a rise which they could not explain. They had expected a fall, because the use of long-term lithium therapy had increased ten-fold during the same period, and they felt that their findings cast doubt on the efficacy of lithium prophylaxis in ordinary clinical practice. Such a conclusion might have far-reaching consequences for patients with recurrent manic-depressive illness, and Dickson & Kendell's analyses merit close scrutiny.

It seems a dubious procedure to draw conclusions about the efficacy of a treatment given to a limited number of patients from admission rates for a much larger number. Not all manic-depressive patients receive prophylactic lithium treatment: it is given only to those with frequent recurrences and is started only after the patients have had several episodes. So even if lithium treatment were 100% effective, it could be expected to prevent only a fraction of the admissions for mania and depression.

Even so, a fall in the admission rate, albeit a small one, would be expected if lithium treatment was the only factor influencing admissions. It obviously was not; powerful forces with an opposite effect must have been at work. Dickson & Kendell examined some factors, such as change in diagnostic fashions or admission thresholds, but were unable to account for the rise. One could think of several others.

Be that as it may, the fact remains that the admission rate for mania and depression showed a pronounced rise, and the rise must have been caused by something. The moderate effect of lithium may

easily have been overshadowed by the marked effect of the unknown factor or factors, and Dickson & Kendell's inference about the poor effect of lithium therapy under ordinary clinical conditions is not vindicated by their data. Examination of rates of readmission for manic-depressive patients actually in long-term lithium treatment might have provided information more suited to assess the efficacy of lithium prophylaxis.

Community Care of the Acutely Mentally Ill

SIR: Whether Hoult's study (*Journal*, August 1986, 149, 137-144) shows that "it is feasible to treat most psychiatric patients in the community as an alternative to mental hospital care" is open to doubt.

For example, 40% of his experimental group required hospital admission at some time. Certainly this was much less, in terms of numbers and duration, than the control sample, but the latter's rates for hospital admission seem inordinately high. It appears that admission was almost automatic for any control group patient turning up at the hospital. Furthermore, there is for some reason a significant increase in neurotic syndrome scores for this control group, and over one fifth are lost to follow up, despite being local residents. It is also worrying that the most diffi-

cult cases in psychiatric practice (those over 65, mentally retarded, brain-damaged and drug/alcohol dependent) are excluded. It is certainly reasonable to have a refined sample for research into aetiology, but assessment of care must surely include all the complicated problems that so often provide the greatest management difficulties. Finally, I am uncertain as to the basis of his costing of the alternative care systems. Does he include the on-call availability of psychiatrists "covering the rest of the catchment area service", and the fixed costs of running a hospital anyway — (regardless of patient usage) — since his patients certainly had to use this resource?

It seems that the problem in this work is the "degree of artificiality" created by a research project. The "assertiveness", 24 hour availability, enthusiasm and job satisfaction of the staff involved are crucial factors, and a false dichotomy between hospital and community care is set up. Yet it is not the "where" that matters, it is the "what" and "who" that are essential. Hoult and his workers have clearly shown that the quality of care, at the personal level, is central to a good outcome in psychiatric illness. They have fallen into the non-scientific trap of obtaining findings that "confirmed our aims" — (where is the null hypothesis in this?) — and have not pursued the obvious control situation, namely putting their motivated research team, and its methods, into the hospital. While it is gratifying to see their success — and the value of having a psychiatrist on-call continually — it may be more realistic to see the hospital as a community resource and not to create either/or contrasts.

A HUNDRED YEARS AGO

Asylum Reports

YORK. DR. HITCHCOCK REPORTS: "During the winter months I have been giving a course of lectures on elementary anatomy, physiology, and the immediate treatment of injuries and accidents, etc to the nurses and attendants of the asylum. I was much gratified by their regular attendance and the interest manifested in the subject; the more so that several, not specially engaged in attendance on the patients, were amongst my class; even some of the patients asked if they

could attend, but I drew the line there. I shall not mind if the knowledge they gained is not tested by practice; but at all events the subject was right and necessary for them to be instructed in, and if all's well I shall give a similar course next year."

Book Reviews

Multiple Personality, Allied Disorders and Hypnosis.

By EUGENE L. BLISS. Oxford: Oxford University Press. 1986. Pp 271. £28.00.

I very much enjoyed reading this book. It combines a scientific review of multiple personality and of hypnosis in which the author puts forward an argument for the conceptualisation of multiple personality as a form of self-hypnosis together with a description of his extensive therapeutic experience with multiple personality using this theoretical framework.

His thesis states that people vary in their capacity for self-hypnosis and some of those who are more gifted have used this ability usually since childhood to cope with traumatic events, by the assumption of a different persona with amnesia for their normal persona. In the less extreme forms of the syndrome they use this facility to share difficulties with one or many alter egos. These subjects almost always show a high capacity for hypnosis as judged both clinically and on the Stanford Hypnotic Susceptibility Scale. The phenomena of hypnosis, e.g. hallucinatory experience, regression, etc. fit readily into the symptomatology of multiple personality.

Professor Bliss argues that far from being an exotic syndrome, the alerted psychiatrist will commonly find cases misdiagnosed under other labels. A substantial number of patients diagnosed as schizophrenic prove to have multiple personality, although he does point out that the patients he investigated had been diagnosed on looser American criteria and not those of the International Study. His therapeutic approach is to gain access to the patient's other personalities through hypnosis and to help them gradually to accept their experience and feelings into normal consciousness and either to integrate all the personalities into his/her own or more usually to arrange a reconciliation between them.

Professor Bliss puts great emphasis on eliciting earlier traumatic experience which has often been sexual and freely acknowledges his debt to Janet and Breuer. His approach has much in common with psychoanalysis in the pursuit of unconscious material, at times by free association. However, he is often directive and uses a variety of other strategies in the therapeutic process.

It seems likely that whatever the arguments about aetiology, his patients find it easier to discuss their problems at arms length by concretising

them into alter egos and the therapist must then use his skills to help the patient to accept the data and its associated feelings into consciousness with subsequent resolution.

It may well be heuristically useful to think more often of the diagnosis of multiple personality in our patients, and challenging to follow the therapeutic path that Professor Bliss has mapped out for us. He emerges from these pages as a very gifted, intuitive and persistent therapist whose example it will not be easy to follow.

OSCAR HILL, *Consultant Psychiatrist, The Middlesex Hospital, London*

Aspects of Epilepsy and Psychiatry. Edited by MICHAEL R. TRIMBLE and TOM G. BOLWIG. Chichester: John Wiley. 1986. Pp 256. £24.50.

In recent years there has been a great increase in the number of books published on epilepsy. One of the editors of this volume, Michael Trimble, has contributed to this change. Is there really more to write that is new, informative and helpful in the management of epilepsy for the psychiatrist? The answer in relation to the present volume must be a qualified 'yes'. Both chapters by Trimble are of value, the observations on hypographia of interest, while those on PET scanning potentially of much greater importance. The hypo-metabolism found in the inter-seizure records in temporal lobe epilepsy, particularly the dominant hemisphere of psychotic patients, is a notable feature. The changes themselves extend beyond the temporal lobe and the limbic system to frontal cortex and the basal ganglia. There is some evidence of a relationship between these reported findings and those in non-epileptic psychotic patients. The electrophysiology of psychosis is dealt with and the puzzling phenomenon of 'forced normalisation' is well reviewed. Emphasis is placed not only on the electrophysiological aspects, previously the main plank of this concept, but giving it a more clinical connotation. There has always been conflict about the possible specificity of personality disorder found in epilepsy as well as whether the temporal lobe seizure disorders have a greater likelihood of psychosis than patients with a primary generalised fit pattern. Here the great knowledge and experience

of Janice Stevens, with information from pathological studies on six cases of epilepsy and psychosis, furnish more evidence to her stance on non-specificity. The difficult topic of aggression in relation to epilepsy is further evaluated but problems still remain. The fact that hypo-sexuality occurs in epilepsy has long been recognised, but the possible underlying hormonal basis is fresher and merits the space afforded by the editors. Clinical aspects such as the impact of chronic handicap and the effects of anticonvulsants are also discussed as well as the treatment of depression, the commonest psychiatric disorder requiring active management with psychotropic drugs. The use of anti-convulsants in non-epileptic conditions is reviewed at length. This remains one of the most controversial areas perhaps requiring less emphasis for the general reader who is otherwise well served by this volume.

D. F. SCOTT, *Department of Neurological Sciences, The London Hospital*

Depression in Young People—Developmental and Clinical Perspectives. By MICHAEL RUTTER and CARROLL E. IZARD. New York: Guilford Press. 1986. Pp 550. £34.50.

The steady growth of interest in depressive disorders in childhood and adolescence is exemplified by this volume, in which developmental and clinical approaches are brought together to present a range of current views and a number of research findings. The 18 chapters have their origins in a 1982 symposium held in the United States, and emphasise development and clinical perspectives. Much of the original material has been revised and brought up to date.

A vast landscape is surveyed here, and the reader will be wise to begin at the beginning. In the prologue, Rutter discusses the developmental psychopathology of depression with customary thoroughness, marshalling the evidence to show that depressive disorders change in form and frequency as children develop into adolescence, and pointing up the clinical distinction between childhood distress of an essentially developmentally normal type, and recognisable depressive disorder which involves biological and cognitive changes, as well as alterations of mood. Contributors to Part 2 examine theoretical approaches to the development of depression, in social, cognitive and biological terms. The risk factor of parental depression is discussed in Part 3, as a genetic influence and as an environmental, day to day presence in the lives of significant numbers of

children. The way in which such parental depression may alter patterns of family interaction receives attention, as does the important question of how affective disorder in a parent may have effects on a child's competence and vulnerability. Risk indices and mechanisms are discussed in Part 4, which also touches on parental loss, stressful life events, and biological factors. Part 5 is concerned with measurement and includes examination of developmental issues in the classification of depression. The work concludes with a forward-looking research postscript.

A number of the contributions particularly attracted your reviewer's attention. Emde, Harmon and Good present a valuable consideration of how depressive feelings may alter during the course of development. Seligman and Peterson demonstrate ways in which the learned helplessness model of depression in adults may also serve as an aetiological model for affective disorder in childhood. There is a comprehensive review of psychobiological research into childhood depression by Puig-Antich, the findings being discussed in relation to what is known of biological markers in adult affective illness. Carlson and Garber's consideration of developmental issues in the classification of depression in children, and Kovacs's examination of the potential of the clinical interview as a tool for the diagnosis of depression, are two especially enjoyable sections.

The editors have largely been successful in steering a safe course between dull uniformity of presentation, and the unevenness which at times can impair large scale multi-author works. Occasionally there is some feeling of repetition across different chapters, but this is balanced by one's satisfaction at the cross-fertilisation which is often apparent, as for example when Dunn, writing on stress, development, and family interaction, amplifies and extends some of the remarks made by Shaffer in his chapter on developmental factors in child and adolescent suicide.

Clinicians are unlikely to find this an easy book, despite the clinical perspective of the title. The practising child and adolescent psychiatrist wondering about how to improve treatment of children and adolescents with affective disorder will not find answers here, for little is said on management. What will be immediately apparent to the reader, however, is the ample stimulation provided for a reconsideration of exactly how the affect of a young person can become disordered, and of the influences which may determine the progress of such disorder. The volume will be important as a work of reference, which should certainly be in every psychiatric library. But it is as a source of ideas, and a guide to some current thinking, that it should ultimately be

considered and on these criteria alone, it deserves the closest attention.

HUGH MORTON, *Consultant Child & Adolescent Psychiatrist, Ninewells Hospital, Dundee*

Alcoholism and Drug Addiction. By D. RAISTRICK and R. DAVIDSON. Edinburgh: Churchill Livingstone. 1985. Pp 198. £18.00.

This is the second volume in the new series of *Current Reviews in Psychiatry*, the editors of which are E. S. Paykel and H. G. Morgan, intended to provide succinct, balanced and topical reviews of the many advances now taking place in psychiatry, for the benefit of postgraduate and practicing clinicians alike. The book consists of 6 chapters, each of which ends with concluding remarks and a list of relevant references, and a 6-page index.

The first is an introductory chapter giving some historical background, a useful account of various terminologies and an interesting model of drug-seeking behaviour. The authors emphasise the importance of a multi-disciplinary approach to the problem of drug dependence as a whole, rather than that of distinction between drugs. This is a philosophy now widely regarded in the biomedical world of drug dependence as the best likely path for advancing our knowledge in this area. In Chapter 2 'Drug Effects and Physical Harm', the authors provide short and useful accounts of factors influencing drug effects as well as descriptions of such effects at the pharmacological and clinical levels. The authors, however, take a somewhat narrow view of the possible mechanism(s) of alcohol dependence and make the erroneous statement that MEOS (the microsomal ethanol-oxidising system) is responsible for the metabolism of certain drugs other than alcohol; they probably mean the microsomal cytochrome P-450-dependent mixed-function oxidase system.

The third chapter 'Psychiatric Disorder' considers psychiatric symptomatology in alcoholism and drug abuse neatly and concisely in relation to the 4 major groups of disorder (affective states, delirium, paranoid psychosis and dysmnestic states) and emphasises the importance of both good knowledge of psychiatry and deeper insight into psychiatric symptoms in alcoholism and drug dependence patients. Chapter 4 'Social Aspects' provides a short historical account and considers aspects such as the integration model, parental attitudes, peer pressure, personal characteristics, environment and the deviance theories. The authors also describe the consequence of misuse of alcohol and drugs and emphasise that a major problem in social research in

this context is that of cause, effect and coincidental findings.

The fifth chapter 'Treatment' considers this aspect in its broad sense, from initial interview to rehabilitation, again emphasising commonalities in the management of both alcohol and drug dependence, and addresses issues such as longitudinal views and studies, current issues in treatment provision, methodological aspects, treatment intensity and setting, patient and therapist characteristics, pharmacological treatments, therapeutic communities and the various psychological approaches to therapy. In Chapter 6 'Prevention', the authors, after a brief account of alcohol and drug consumption, discuss control strategies, alcohol availability and fiscal measures, then move on to prevention strategies (education, media campaigns and advertising), emphasising the need to consider a number of important research and policy issues in this context and to develop a comprehensive and informed prevention policy.

This book is well written and nicely produced, with very few typographical errors, and its content will provide an easy and concise introduction to the psychiatric student of alcoholism and drug dependence.

A. A.-B. BADAWY, *Top-Grade Biochemist, Whitchurch Hospital, Cardiff*

Psychology for Social Workers. Revised 2nd edition.

By MARTIN HERBERT. Basingstoke: Macmillan. 1986. Pp 322. £18.00 hb, £7.95 pb.

Psychology for Social Workers is one of a series of books published by the British Psychological Society. The stated aim of the series is to "... illustrate how psychology can be applied in particular professional contexts, [and] how it can increase the skills of practitioners..." A worthwhile aim which bears somewhat patchy fruit on this occasion.

The current volume is arranged into two parts. The first, written by the author Martin Herbert, sets about describing the clinical psychologist's basic set of concepts. Thereby, we are introduced to the terminology of the psychologist; and perhaps more importantly, to the basic assumption on which this discipline rests. That is, the psychologist begins with a person's behaviour. Whilst there is interest shown in the motives which arise from inner world factors, such as feelings, fantasies, needs and so on, the emphasis is on how current behaviours are reinforced and can be used to predict how a person may behave in the future. The implication is that the practitioner can thus devise strategies to change particular behaviour patterns.

The second and most extensive part, includes contributions from a range of authors who attempt to link psychological theory to specific areas of practice. These include a number of contexts where social workers would expect to find themselves; for example, in institutions, or in casework with the aged, those people who are dying and bereaved, and with families. This seems to be an attempt to describe how theories of psychology can be used to orient social workers in their *thinking* about their practice. Useful illustrations of this will be found in the chapters on The Behavioural Casework Approach (Ch.11) and Counselling and Helping (Ch.12).

From a practicing social worker's point of view, the major limitations of this book lie in the case illustrations. It appears that the authors are mostly based in educational or training settings, and this may account for some of the textbook flavour to be found. With this in mind, I would have little hesitation in saying that students who are training as social workers, and professionals in the medical world, will find this a useful companion to their lectures and seminars on the theory of psychology.

PETER FULLERTON, *Psychiatric Social Worker, The Emanuel Muller Clinic for Families and Children, London*

Schizophrenia: An Integrative View. Edited by C. L. CAZULLO and G. INVERNIZZI. London: John Libbey. 1985. Pp 402. £22.00.

This volume, which forms part of a series entitled *Biological Psychiatry—New Prospects* is a collection of papers from a conference held in Milan in June 1984. 42 papers by 101 authors, 66 of them Italian, are included.

The papers are arranged in four parts. The first, 'Cultural and Social Aspects' opens with a paper by the senior editor that attempts to live up to the book's title by incorporating discussion of symptom pattern, lithium, social intervention and movement related brain macropotentials to conclude that "a mental disorder like schizophrenia can be understood by an interpersonal approach and consequently has to be always treated within an interpersonal relationship". This section is devoted mainly to brief essays on epistemology and there is little presentation or analysis of scientific data. Hamilton's brief but sparkling discussion of the influence on the historical development of ideas of the world of schizophrenic thought disorder is, however, a delight.

The second section 'The Psychic Milieu' contains a good review by Andreasen of recent progress in

increasing the reliability of measures of schizophrenic symptoms, and of the persistent problems in the diagnosis and subclassification of the disease. Also interesting is Invernizzi on psychodynamic aspects of psychosis following kidney transplantation.

The third and meatiest section is on 'Biological Aspects'; the best of these papers, by Shagass *et al* on brain electrical potentials, and by Nurnberger *et al* on genetic markers, combine scholarly review with presentations of original research data. The final part, 'Integrative Strategies for Treatment' is thinnest on the ground, though there is a clear review by Maj and Kemali of the developing concept of schizoaffective disorders and an extraordinary essay by Reda on the history of 'shock' treatment which includes fuzzy illustrations of a 'rotating chair' and of 'synapsis: a microscopic world of the cerebral galaxy which fascinates and worries us'.

The book has no editorial introduction and, indeed, little evidence of editorial intervention. Though some of the papers are worth reading, many are of only local interest and the translation from the Italian is often poor. The typewritten text is unattractive, misprints abound, and the binding is flimsy. My copy had several pages uncut, a section omitted, and another duplicated. Though its price is, by today's standards, quite low, I cannot wholeheartedly recommend this volume either to individuals or to libraries.

C. L. E. KATONA, *Senior Lecturer in Psychiatry, Middlesex Hospital, London*

The Substance Abuse Problems. Vol 2. New Issues for the 1980's. By SIDNEY COHEN. The Haworth Press: New York. 1985. Pp 323. \$34.95 h/b \$19.95 p/b.

The essays are in many cases revisions of contributions to a drug abuse and alcoholism newsletter and none the worse for that. However, they are of somewhat variable quality and Dr Cohen would not I am sure claim that this is intended as a textbook. As a reader, based on the very wide and considerable experience of a psychiatrist, well known both for his academic contributions and his concern for patients, it is well worth reading. Prominence is given to the drug, cocaine. This currently presents new problems on both sides of the atlantic, by reason of increasing availability, social acceptability and by the development of more potent forms, in particular the treatment of cocaine hydrochloride with alkali and then extracting it with solvents to produce a volatile preparation "cocaine free base" which can be consumed by heating and then inhaling, producing a very rapid effect. Dr Cohen draws attention to the

importance of the method of consumption in facilitating compulsive use which he promulgates as a general law whereby techniques or drugs that produce more intense and immediate effect tend to displace those that provide slower or more moderate effects. A useful chapter on management of compulsive cocaine use stresses the value of working with the family and assisting relatives in setting clear limits and neither directly nor indirectly financing a continued drug habit. He raises the possibility of a management technique not common in this country, described as contingency contracting whereby the patient/client writes a confession regarding their behaviour, with instructions that this should be mailed to some important other agency such as law enforcement or employer should they break their contract of continued treatment and abstinence. While this may seem excessively authoritarian it should be noted that the most successful alcohol problem treatment services are operated by employers, and particularly by the Armed Forces, where the consequence of relapse is clear, but the advantages of success are assured by the employer. Throughout the book Dr Cohen is eminently balanced in his comparison of illegal drugs with alcohol and tobacco, and there are extensive contributions on alcohol issues. A series of articles examine the evidence for controlled drinking and Dr Cohen provides his own personal criticism regarding the controversy surrounding the work of Sobels, whereby he stresses that the subsequent progress of the patients is the important issue rather than arguments regarding the detailed proprieties of the research. In general some of the most enjoyable aspects of the book are his pithy and refreshing personal comments, thus when considering the evidence for genetic factors in the aetiology of alcoholism he comments that this certainly has one advantage "one can always blame it on one's chromosomes" and "people with problems of loss of control must either: abstain completely; learn stratagems of maintaining control; or accept inevitable alcoholism". An essay of great value concerns training non-psychiatric workers in the importance and techniques of early identification of alcohol problems.

MARTIN MITCHESON, *Consultant Psychiatrist, County Hospital, Hereford*

The Psychoanalytic Study of the Child. Edited by ALBERT J. SOLNIT, RUTH S. EISSLER and PETER B. NEUBAUER. London: Yale University Press. 1985. Pp 568. £45.00.

This is the latest volume of an annual publication founded by Anna Freud, Heinz Hartmann and Ernst

Kris, originally centred around child psychoanalysis and the ways in which psychoanalytic concepts furthered the understanding of the development of children from the first weeks into adulthood. Previous volumes have contained many important contributions to psychoanalysis and analytical psychotherapy, as evidenced by the publication's survival for over forty years.

The volume is for those interested in analytically-oriented psychotherapy. In spite of its title the book is as relevant to those in adult psychotherapy as it is to those working with children. There are papers comparing adult analysis to child analysis, therapy of homosexual men, two papers on working with parent and child, two papers on the effects of siblings on development (one concerning the effect of having a handicapped sibling), a study of children raised by their fathers as primary care giver, the problems adoption poses to families (including suggestions about "when to tell"), a disturbing paper about psychic trauma (e.g. surviving the Tenerife Air Disaster) and its relation to ghosts and feeling haunted, and several other equally worthy of mention. All of these contain good clinical material, often spanning several years of therapy.

Three or four of the contributions are primarily theoretical. In line with the mostly USA based authorship, these papers are concerned with developing Freudian metapsychology and ego-psychology, a framework which is not so commonly adhered to in Britain.

The Applied section of the volume, in addition to some of the papers already referred to, contains five papers for the general reader interested in the understanding (and limitations) which psychoanalytic concepts can bring to art and the nature of creativity.

Overall, I found the volume enjoyable, readable and informative. It is probably not for the pre-membership psychiatrist. Those who do not normally work in an analytically-oriented way in psychotherapy should skip some of the papers, but not be put off the volume as a whole.

TOM MURPHY, *Consultant Psychotherapist, Royal Dundee Liff Hospital, Angus*

Testing Psychological Tests. By DOUGLAS SHELLEY and DAVID COHEN. Kent: Croom Helm. 1986. Pp. 203. £17.50 (hb), £8.95 (pb).

Although written in an easy to read, journalistic style the authors seek to address themselves to some serious questions concerning psychological testing. These include the possibility of generalising from laboratory to real-life settings, 'consistency' both of people and of tests; different types of validity, sampling and reliability. The book is laid

out clearly, each chapter containing a series of 'case histories' to illustrate points, quotations from papers and concluding remarks.

The authors' aim is not to write a 'which' guide to testing but to examine features and limitations of both well known and unusual psychological tests. A chapter on newspaper and magazine 'tests' is also included, showing how badly these are often constructed and how sweeping their claims usually are. The book is amusing and provocative, written with the general rather than specialist reader in mind. The chapters vary in interest and quality, the first and last being the best in my opinion.

The authors comment on the 'middle class' bias of many existing tests and the inappropriateness of U.S. student norms. They offer interesting and practical suggestions for designing new assessment tools and improving current ones to make them more relevant to present day needs. The book should succeed in making the reader question statements about psychological testing.

SUSANNE REIMAN, *Senior Clinical Psychologist,
The London Hospital (Whitechapel)*

Culture and Depression: Studies in the Anthropology and Cross-Cultural Psychiatry of Affect and Disorder. Edited by ARTHUR KLEINMAN and BYRON GOOD. London: University of California Press. 1985. Pp. 535. £38.25

Depression as an illness and depression as a mood or symptom is explored in this volume by psychiatrists and anthropologists

Religious and social expectations in various cultures and their influence on depressive affect and disorder are investigated and categorised under historical, cognitive and epidemiological headings with a useful, final, integrating category.

Historically Christians seemed to have viewed depression as an example of 'bad' behaviour caused in the devout by the conflict between a desire for spiritual perfection and man's fleshly inclinations. Manual labour, social rejection or occasionally a 'gentle soothing approach' is recommended. Buddhism on the other hand takes the view that depressive mood characterised by hopelessness, distress and shame is a valued state since it leads to salvation achieved through a greater understanding of the nature of the world.

Attempts are made throughout the book to construct a universal paradigm for depressive emotion and disorder through the interaction of psychocultural and biosocial factors. This leads to the appreciation of the phenomenologies of depression as soul loss, existential despair, somatic distress and possession states.

Affect is also considered as rhetoric and as a stylistic characteristic of speech with metacommunicational markers which adds to the understanding of depression through the analysis of discourse. But the sociolinguistic paradigm poses questions for which disappointingly as yet no answers are available. Culture rather than biology encourages the reader to consider a final common ethno-behavioural pathway rather than the usually accepted biological one.

The editors are to be congratulated on bringing together many stimulating papers on the social and psychological causes of depression. This is an impressive work of scholarship and recommended for all those who seek to extend the boundaries of their understanding of this subject.

DENNIS FRIEDMAN, *Visiting Consultant,
The Priory Hospital, London*

Adolescent Relations with Mothers, Fathers and Friends. By JAMES YOUNISS and JACQUELINE SMOLLAR. London: The University of Chicago Press. 1985. Pp. 201. £21.25.

This American book describes the accumulated findings of eight different surveys carried out in recent years on the peer and family relationships of 1049 normal adolescents aged 14 to 19 years living in the United States.

It begins with a very useful and up-to-date introduction to the relevant literature, but major British work (eg Coleman) receives scant attention, and comparison with the findings of Offer's studies proves difficult. The importance of understanding adolescent relationships within the context of a family system is recognised in the writing up of the studies, but played no part in their original design nor in the interpretation of results. The book's primary contribution is therefore to the sociology of normal adolescence, and few of the findings have implications for clinical psychiatry.

It is not difficult to read and the structure of the book helps. Detailed descriptions of the research designs are mercifully largely confined to a single chapter, and the following eight chapters consist of five, describing results, interspersed by three summarising/discussion chapters. Taken with earlier work, the findings establish beyond reasonable doubt that for most adolescents the process of emancipation and establishing an adult identity is associated with a transformation of, rather than the detachment from, parental respect and relationship ties. Agreeing with Piaget's concept of autonomy, "autonomy . . . appears only with reciprocity", they found it to be one of the most crucial aspects of adolescent friendships, permitting joint exploration and understanding of reality.

Piaget and Sullivan are obviously profound influences, and it is possibly unfair to criticise the absence of any consideration of object-relations theory or modern ego psychology, or even the influence on adolescent family relationships of parental morbidity; however, the absence of any examination of the effects of unemployment, or membership of ethnic minorities, on the pattern of adolescent relationships seemed surprising omissions.

A book to be recommended for the library rather than for personal purchase.

R. M. WRATE, *Consultant in Adolescent Psychiatry,
Royal Edinburgh Hospital, Edinburgh*

Art Therapy for Groups: The Handbook of Themes, Games and Exercises. By MARIAN LIEBMAN. Beckenham Croom Helm. 1986. Pp. 226. £9.95.

This is an excellent, stimulating account by an experienced art therapist of how and with what result this approach may

be used in groups. The author has drawn on the experience of other therapists in the field, especially those in the Bristol area. Sensible advice is given in part one on how groups differ, may be composed and art integrated into sessions or workshops. The second part comprises brief descriptions of nearly 300 themes, games and exercises that the leader may suggest as ways of exploring group interaction, family relationships, and particularly well done, self-perceptions; the approaches may also be used to improve concentration, dexterity and memory. There are good suggestions for further reading.

This book is aimed at a wide range of practitioners whose caring profession may be as teachers, social workers, youth and community group workers and the new, separate profession within the N.H.S. of art therapists. Art is used as a means of personal expression to communicate feelings. The leader does not interpret the content, but helps the individual to let the picture 'speak back', and reveal aspects of its personal meaning. However, it is clear that personal issues of great complexity may surface and powerful group dynamics may be engaged. While the leader is strongly advised to seek supervision, especially if working in a clinical setting, consideration of the literature on individual and group dynamics only occupies 3 pages out of 225. This imbalance is worrying and reflects a deficiency in the formal training of art therapists. As the author states, the suggested activities are like tools which may be used constructively or destructively, clumsily or skillfully. Experience is one guide to their use. For the reviewer, supervision and knowledge of the established literature on human interaction are the others.

MARK AVELINE, *Consultant Psychotherapist,
Nottingham Psychotherapy Unit*

Negative Outcome in Psychotherapy and What to do About It. Edited by DANIEL T. MAYS and CYRIL M. FRANKS. New York: Springer Publishing, 1985. Pp. 365. \$34.95.

This book is a wide-ranging study of deterioration occurring in patients during the course of psychotherapy. It is specifically interested in negative outcome as opposed to treatment failure which of course would be 'zero outcome'. A major inference of proven negative outcome is that the treatment approach in question is a powerful one, which might have both positive and/or negative effects under certain conditions. A debate is still going on as to whether patients undergoing one of the psychotherapies not only improve more but also deteriorate more than those patients in a control group. The editors of this book contribute to this debate and come down on the side of no increased deterioration proven for treatment groups versus control groups in a large number of studies.

The book is tidily organised under the following headings, Introduction; Negative Outcome and Therapeutic Modality; Negative Outcome and Patient Population; Negative Outcome: Parameters and Special Considerations; Conclusions and Implications. The sum total of the book involves a wide study of therapist, patient and other variables which may lead to a deterioration effect. It ends with consideration being given to ways in which the risk of

patients becoming worse may be reduced. Overall, I found the first half of the book useful and illuminating with a marked deterioration occurring in the middle section. The editors themselves returned to save the day in the 'Conclusion' section. The research based chapters one and two, 'Negative Outcome: Historical Context and Definitional Issues' by Mays and Franks, and 'Negative Effects and Their Determinants' by Strupp and Hadley, I found to be closely argued, well researched, and thought-provoking.

The chapters by Dies and Teleska on Group Psychotherapy, Horne on Anorexia Nervosa, Vaughan and Beech on Obsessionals and Hollon and Emerson on Depressive Disorders, I found to be of poorer quality. These were more anecdotal and ruminative, providing far less research evidence and very often indicated more interest in the zero response (no change) than the negative response (deterioration). A chapter by Thoits on the 'Influence of Factors Outside Therapy', I found to be a useful reminder of the fact that one must always be on the alert for the interaction between our clients' inner and outer worlds.

There is also an anachronistic little article by Eysenck attempting to develop a theoretical framework for negative outcome using Pavlovian psychology. It seemed strangely out of place in these pages.

Overall, the good aspects of the book outweigh the bad and I would like to recommend it to those interested in the clinical and research aspects of those patients who deteriorate in the course of their psychotherapy.

J. P. ROBERTS, *Consultant Psychotherapist,
The London Hospital*

A Comprehensive Approach to the Treatment of Normal Weight Bulimia. Edited by WALTER H. KAYE and HARRY E. GWIRTSMAN. Washington: American Psychiatric Press, 1985. Pp. 131. \$12.00.

This is one of the first books devoted exclusively to the treatment of bulimia nervosa. It consists of seven review chapters each written by recognised authorities in the field. The book opens with two introductory chapters. The first outlines the clinical features of bulimia nervosa and the little that is known about its prevalence. This is followed by a description of some novel observation work on the over-eating of these patients. In the third chapter, which is concerned with the medical implications of bulimia nervosa, it is gratifying to see the eponym 'Russell's sign' being proposed for the characteristic abrasions and scars on the hands of those who regularly use their fingers to induce vomiting. There are few physical signs in psychiatry and it is entirely appropriate that this one is named after Professor Russell who has contributed so much to our understanding of the disorder. The remaining four chapters are devoted to treatment. The first by Yager and Edelman is an excellent description of the various approaches to the management of bulimia nervosa. It considers both assessment and treatment and examines the respective roles of psychological and pharmacological approaches. This chapter can be strongly recommended to anyone wanting an overview on the management of the disorder. It is followed by chapters on group therapy and in-patient treatment. The latter is especially

interesting since it provides a clear description of an in-patient management programme. Hospitalisation is rarely appropriate for patients with bulimia nervosa, but in some cases it is unavoidable. Almost invariably in-patient treatment proves difficult. This chapter describes how some of these difficulties may be overcome. The final chapter is concerned with the use of anti-depressant drugs. Unfortunately its authors are somewhat uncritical when describing the studies which support the use of these drugs and it is particularly regrettable that they omit to point out that there has been no systematic research into their long-term use.

This brief and relatively inexpensive book is a welcome addition to the literature on bulimia nervosa since it contains a number of useful reviews on several different forms of treatment. It would perhaps have been improved by the inclusion of two additional chapters: first, one on the diagnosis of bulimia nervosa since several different diagnostic schemes are currently in use; and second, a chapter on cognitive behavioural treatments since a mounting body of evidence suggests that they are one of the most effective ways of helping many of these patients.

CHRISTOPHER G. FAIRBURN, *Wellcome Trust Senior Lecturer, Department of Psychiatry, University of Oxford*

Psychological Disorders in Obstetrics and Gynaecology. Edited by R. G. PRIEST. Sevenoaks: The Butterworth Group. 1985. Pp. 236. £32.00.

A review of the many psychological problems that are found within obstetrics and gynaecology has been needed for some time. This book covers this subject very fully indeed and Professor Priest must be congratulated for assembling a list of authors whose contributions are comprehensive, detailed and immensely readable. Written entirely by psychiatrists this publication covers not only the psychological problems caused by pregnancy and obstetric and gynaecological problems in general, but it also discusses the psychological disorders that may present with gynaecological symptoms. The book begins with an excellent survey of sexual dysfunction and the psychological causes of infertility, and is followed by a clear and factual discussion of the emotional and psychological problems that may result from gynaecological surgery, in particular hysterectomy. One is pleased to see, at long last, an objective and well balanced review of these emotive subjects. The difficult problems of pelvic pain and premenstrual syndrome are discussed at some length but the largest chapter in this book is concerned with the psychological disorders that may be associated with pregnancy. This very comprehensive contribution is clear, well referenced and immensely informative. Many of the sections in this book illustrate their text with case reports and such reports were particularly helpful in relation to pregnancy. Further equally excellent sections in this book cover the puerperium and termination of pregnancy. The last chapter concerns itself with the menopause, where the psychiatric problems, said to be associated with the menopause, are objectively evaluated.

This splendid contribution to the literature must surely be of interest to all those psychiatrists involved with obstetric and gynaecological patients. It certainly should be mandatory reading for all obstetricians and gynaecologists, and I hope that this book will come to hold an important and respected position on the shelves of all medical libraries.

ANNE M. JEQUIER, *Senior Lecturer, Queen's Medical Centre, Nottingham*

Susto, A Folk Illness. By J. ARTHUR, CARL W. O'NEIL and ROLANDO COLLANDO-ARDON. Berkeley: University of California Press. Pp. 186. \$22.95.

This book is an interesting attempt by two anthropologists and a physician to carry out a study of the folk-illness 'Susto' in three adjacent communities in Mexico.

The authors in a useful introductory chapter, make the point clearly that this folk illness should not be encapsulated within pre-arranged Western diagnostic categories. They have started, therefore, with the local belief that Susto is caused by separation of soul and body which is precipitated by the intervention of a supernatural force. They have then compared patients who complained of having Susto with a local matched control group. Furthermore they have acknowledged that a proportion of patients with Susto might be suffering from a physical illness or indeed, have a clear cut psychiatric disorder. In a novel way, therefore, the authors have juxtaposed anthropological, physical and psychiatric clinical approaches and so highlighted the contrast between the medical and the ethnographic paradigms.

Inevitably, difficulties with this combined approach were encountered. There was a problem translating the Langner 22 item scale into the local language and the limitations of this scale became readily apparent. Thus no differences were found in scores on the Langner scale between the Susto patient and control although, using crude clinical categories of psychiatric disorder, Susto patients were more likely to be emotionally disturbed.

It is a pity that the authors did not include a research psychiatrist on their team.

Nevertheless, the book is worth reading by anyone who is about to embark on a study which will involve close collaboration between social anthropologists, psychiatrists and physicians. The authors have courageously attempted to combine social anthropological research methodology with behavioural science measures. In this way they have pioneered a collaboration, from which others will learn.

This collaboration is indeed vitally important, but, as the authors have found, is very difficult to carry out. The account of the attempt made to overcome the difficulties and the full details of the questionnaires used that are included in the appendix makes the book worth buying, or certainly borrowing from a local library.

Classification of affective disorders

The influence of periodicity on the classification of affective disorders

Dr C. Thompson, Charing Cross Hospital, London

Periodicity, the regularity of occurrence of affective episodes, has been seen as an important property of affective disorders since they were first distinguished from schizophrenia by Kraepelin (1921). The value of periodicity in the classification of affective disorders is discussed, and recent attempts to use periodicity in a different way is described.

The Newcastle scale and measurement in depression

Dr M. W. P. Carney, Northwick Park Hospital, Middlesex

Fresh evidence in the long-running debate between the monist and dualist views of the classification of depression is presented. The Newcastle Scale (for the differentiation of endogenous from neurotic depression) scores of a group of 64 and sub-sample of 52 severely depressed in-patients were found to be not normally distributed, the scores of the sub-sample of 52 assuming a typical bimodal distribution. Though the shape of the distribution curve is not accepted as conclusive, evidence for discontinuity in these distributions was adduced from the contrast in outcome between the endogenous (with Newcastle scores greater than 5) and neurotic (with Newcastle scores of 5 or less) patients thus defined, the endogenous patients faring consistently better than the neurotic group. On the other hand, the unipolar/bipolar system of classification failed to predict a differential outcome in a sub-group of patients, unless the unipolar was divided by Newcastle score into endogenous unipolar and neurotic unipolar. The DSMIII criteria for major depression and melancholia failed to identify sub-groups of differing prognosis. It is concluded that the distinction between endogenous and neurotic depressions as judged by Newcastle score has validity in terms of clinical outcome and is not to be confused with severity of depression.

The WHO study on the dexamethasone suppression test

Dr A. Coppen, MRC Neuropsychiatry Research Laboratory, Surrey

A large study was carried out by the World Health Organization in order to examine the incidence of an abnormal response to the dexamethasone suppression test among depressive patients. Thirteen research centres, representing 12 different countries, took part in the study. Plasma samples from 543 patients and 246 healthy controls were assayed at the MRC Neuropsychiatry Laboratory in Epsom. The results showed variation between centres, but in most of them the percentage of depressive patients with an abnormal DST response was much higher than in the controls.

French diagnostic practices in the field of affective disorders

Professor C. Pull, Centre Hospitalier de Luxembourg

In the French classification of mental diseases, elaborated by the Institut National de la Santé et de la Recherche

Médicale (INSERM), depressive disorder is listed in the three following categories: manic and depressive psychoses (INSERM O1) with basically only two sub-categories, i.e. the melancholic episodes of manic-depressive psychosis and involuntional melancholia; non-psychotic depressions (INSERM 13) subdivided in neurotic and reactive depressions; and chronic schizophrenia (INSERM O2) which presents a sub-category termed chronic schizophrenia with depression, or atypical depression.

The INSERM classification is a simple nomenclature which provides neither glossary like ICD-9 nor diagnostic criteria like DSM III. As a consequence, it would make little sense to proceed to direct comparisons between the French and any other classification system. In the present report, comparisons are based on a poly-diagnostic approach, in which clinical diagnosis is documented by means of a standardised list (LICET-D 100) which integrates the diagnostic criteria proposed in a number of recent classification systems.

In 1984, a survey was carried out in a sample group representative of French psychiatrists. The group consisted of 50 qualified psychiatrists who had previously collaborated in similar studies. The participants were invited to provide several cases of depressive patients diagnosed according to the INSERM classification. No criteria were imposed to make a diagnosis. The only requests were that the clinicians should be reasonably positive about their diagnoses and that they should document their diagnoses using a set of internationally understandable criteria.

This report presents the first results of this investigation.

Mental handicap

A study of the socio demographic, familial and clinical factors associated with the admission of the mentally handicapped to hospital

Dr J. M. Rao, University of Wales College of Medicine, Cardiff

The case records of 293 mentally handicapped persons admitted to Ely Hospital over a 10 year period were examined and four categories of information were recorded comprising demographic data, sources of referral, reasons for referral and family factors. A preliminary analysis indicated that the majority of those admitted came from socio-economically disadvantaged circumstances. More than half the total sample had severe mental handicap and a large proportion had physical handicap as well. More than half had behavioural problems and a quarter had medical problems leading to admissions. A large proportion of families suffered stress from a concatenation of causes. A considerable number of families lacked intellectual, emotional or material resources. It was thus evident that the need for admission to hospital in a majority of cases arose as a result of not only severe handicap and behavioural, medical problems but also due to adverse influences in the family environment.

Lessons to be learned from closing a hospital for the mentally handicapped*Dr Lorna Wing, Institute of Psychiatry, London*

The effects on the residents of the run down of Darenth Park adult mental handicap hospital are being evaluated. The behaviour, skills and life styles of those who move, and of individually matched controls temporarily remaining in the hospital, are being recorded shortly before moving and one year later. Data are collected by interviewing residents, staff and relatives and observation and psychological testing of residents. Since 1980, before the opening of planned, locally based DHA facilities, over 250 have been placed in various NHS, social service, voluntary and private establishments throughout S.E. England. These *ad hoc* placements have led to improvements in life style for some, deterioration for others and no change for the rest.

The lessons learned from such placements include the following. It is difficult to move out of hospital those residents with severe impairments of social interaction and communication, poor skills and difficult behaviour. Future plans for hospital closures should ensure that, from the start, movers should include difficult as well as amenable people, to avoid creating a residue of those with severe problems. A slow run down causes great anxiety to many who understand what is happening, especially older, long-stay residents. Careful preparation and, where possible, explanation are necessary to help residents settle in new placements. Sudden removals to new units cause much distress. It is easy for those organising new services to be unaware of long and deep friendships between residents, and separation of such friends of the same or opposite sex can lead to much unhappiness and depression. Those living outside hospital have fewer amenities provided free of charge, which leads to personal money problems. Placement in old people's homes of mentally handicapped people who are elderly but not demented often proves to be inappropriate.

For all levels of handicaps, small living units with adequate staffing levels, staff autonomy and a flexible organisation are necessary for, but do not, of themselves, guarantee a lifestyle with more opportunities for occupation, education and leisure. However such units do not appear to lead to increase in skills nor much change in behaviour. The effects on people with different types of handicaps of living in ordinary houses in groups of two, three or four people have still to be evaluated.

Developments in parasuicide**The problems of assessing the epidemiology of suicide and parasuicide***Dr R. D. T. Farmer, Westminster Medical School, London*

Epidemiology is concerned with investigating the causes and natural history of diseases by studying their behaviour in populations. This involves exploring the relationship between the disease under investigation and temporal, social and personal variables. The fundamental problem encountered with the study of suicide and parasuicide is that neither comply with generally accepted concepts of disease. Suicide is the termination of a person's life as a result of actions initiated by the individual with the deliberate and conscious intent of achieving death. Parasuicide is

a non-fatal self-injury usually initiated without the intent of achieving death. Both definitions depend on making assumptions about the motive and outcome of an act.

In order to establish a suicide it has first to be recognised as due to other than natural causes. In England and Wales investigation of unnatural deaths is the responsibility of the Coroner who is bound by rules of evidence; in Scotland the Procurator Fiscal has this responsibility; he has a different set of rules. In much of Europe medical certification of cause is separated from the processes of criminal investigation. Consequently, international comparative studies present major problems.

There is no widely recognised prodromal symptom complex that can be said to be the 'early stages' of suicide. The suicide only becomes apparent after death has occurred; the parasuicide becomes apparent after the event (provided that the injury justified hospital attendance) and the patient is, by definition, alive, because the dead cannot be interviewed. Clearly there must be a relationship between suicide and parasuicide but the exploration of this relationship is hampered by the inescapable fact that the two phenomena cannot be investigated using the same methodology. From the point of view of the clinician this fact has only marginal relevance but from the standpoint of an epidemiologist it is of critical importance. Ways of overcoming some of these problems are discussed.

Long-term outcome of attempted suicide*D. K. Hawton, Warneford Hospital, Oxford*

People who make suicide attempts are a very heterogeneous population—the common factor being their having all engaged in this form of behaviour. Except in comparative research (as in treatment studies), the most meaningful way of examining outcome is in terms of subsequent suicidal behaviour. This paper is largely concerned with repetition of attempts and with eventual completed suicide.

Between 12% and 25% of attempters make repeat attempts within a year of a previous attempt, repeats most commonly occurring during the first three months. A particularly problematical group are chronic repeaters, who have a high risk of eventual suicide. Although risk factors for repetition have been identified, special treatment services have had no effect on repetition rates.

A recent long-term follow-up study of a large group of suicide attempters has demonstrated that death rates are exceptionally high, because of both eventual suicide and death from other causes. During the first year the suicide rate was one hundred times that of the general population, but remained high throughout the nine year follow-up. Suicides were distinguished from survivors in terms of being older, poor physical health, psychiatric disorder, especially chronic psychiatric illness, long-term use of hypnotics, and less often having made their attempts following a major row or the break-up of a relationship with a partner. Death from circulatory, respiratory and endocrine disorders were also far higher than expected. This may be explained partly in terms of physical illness and contributing to suicidal behaviour and partly in terms of the stressful life-styles of those individuals.

Outcome of attempted suicide*Dr Jouko Lonnqvist, Associate Professor of Psychiatry, Helsinki University, Tukholmankatu 8 C, 00290 Helsinki, Finland*

Preliminary results of a study which comprises 3,265 consecutive suicide attempts at the emergency departments of Helsinki University Central Hospital in 1973-79, and for whom a psychiatric consultation was arranged, are given. In addition to demographic data, lethality and intent to die and the intensity of the further psychiatric treatment was assessed. By the end of the follow-up period (1973-80) 305 patients had died, 217 of them male and 88 female. In 49.8% the cause of death was suicide. The suicide rate among males (7.8%) was much higher than among females (2.3%). The risk of suicide by age among males is highest (8.7%) for those under 20. Lethality and intent clearly distinguish between attempts in terms of the risk of suicide. The amount of suicides was 2.9% for mild, 4.7% for moderate and 8.4% for severe lethality (somatic severity) and 3.0% for mild, 4.3% for moderate and 7.8% for severe intent to die. In cases of severe intent the risk of suicide during the first year of follow-up is much higher (5.0%) than for moderate (2.1%) or mild (1.2%) intent.

The intensity of further psychiatric treatment correlates with the suicide rate during the follow-up period. Proportion of suicides was 7.7% for compulsory hospital treatment and 6.6% for voluntary hospital treatment, from 3.6% to 4.6% in different outpatient facilities and 2.0% for those who had not received any psychiatric treatment.

Recent clinical and epidemiological trends in parasuicide: A tale of two cities

Drs Stephen Platt, MRC Unit for Epidemiological Studies in Psychiatry, Edinburgh and Keith Hawton, Warneford Hospital, Oxford

This paper presents a comparative analysis of trends in parasuicide among hospital treated patients in Edinburgh and Oxford, 1976-84. Over the period the overall parasuicide rate declined in both cities, but more markedly among women than men. While the female rate was consistently higher than the male rate, there was some suggestion that the female:male ratio was becoming more equal in Edinburgh. Among men, the rate in Edinburgh was significantly higher than the rate in Oxford, while the rates among women in both cities were similar over the years and significantly correlated. An analysis of rates by age group in 1983-84 shows the familiar inverse relationship with rates tending to decline with increasing age. However, this pattern was more marked among females in both cities (rates peaking in the 15-19 age group), while the highest rate among males was in the 20-24 age group in Edinburgh and in the 25-34 age group in Oxford. Over the study period there was a marked fall in the rate in Oxford among males aged 45+ years and women aged 55+ years. Among men in both cities rates were lowest among the married and highest among the divorced, while the pattern for women was somewhat different: lowest among the widowed and highest among the divorced (Edinburgh) or among the single (Oxford). There was a strong inverse relationship with social class, and a marked increase in parasuicide among the unemployed compared to the employed, for women as well as for men.

Major clinical features included: a higher short-term repetition rate for Edinburgh men compared to Oxford men; a dramatic decline over time in the use of barbiturates and a marked increase in the use of non-opiate analgesics, particularly paracetamol; a greater proportion of the Oxford sample reporting previous psychiatric treatment

and alcohol problems, but use of alcohol at the time of parasuicide being more prevalent in Edinburgh; and a significant variation in the pattern of aftercare between Edinburgh and Oxford, with more use of outpatient facilities in Oxford and greater reliance on the general practitioner in Edinburgh.

Mental illness and the temporal lobe

The neuropathology of temporal lobectomy

Dr J. C. Bruton, Department of Neuropathology, Runwell Hospital, Essex

The study presented is a clinico-pathological survey of 249 temporal lobectomy cases operated upon by Mr Murray Falconer, during the 25 years beginning 1 January 1950.

The first aim was to identify the appearances, nature and behaviour of the various abnormalities found in the resected lobes, and in order to do this it was considered beneficial to modify to some extent the current system of neuropathological nomenclature of the temporal lobe lesions.

The second object was to identify, if possible, those patients most likely to benefit from temporal lobe surgery, using follow-up information which had been collected in some patients for almost 25 years.

The results of the survey have been encouraging in that the revised system of classification appears not only to highlight certain differences between lesions, showing that some behave as neoplasms, whilst others are maldevelopmental, but it also enables the formation of a 'league table of benefit from surgery' which may be of use to clinicians who deal with these cases.

The results confirm that patients who have the commonest lesion (Ammon's horn sclerosis) are likely to benefit greatly from surgery. Other less common lesions, such as the mixed glial and the ganglioglioma malformations, also do well. However, three groups were significantly worse after operation; these were the patients with post-traumatic damage, those with indefinite pathology and those with no demonstrable pathology at all.

During the survey, details of psychiatric illness and of post-operative social adjustment to life were recorded and certain significant changes were seen. The presentation concentrates, to a certain extent, on these psychiatric features.

Limbic pathology in schizophrenia

Dr B. Bogerts, Department of Psychiatry, University of Dusseldorf, West Germany

In order to determine whether ventricular enlargement in schizophrenics is due to a general brain atrophy or to a more regionally confined reduction of brain tissue, CT scans and post mortem brains of schizophrenics were evaluated morphometrically.

(a) *CT scans.* The size of all cortical sulci, the Sylvian fissure, lateral, third and fourth ventricles of 54 schizophrenics (ICD 9 295.0-6) and 54 controls matched for age and sex were determined by blind planimetry. The left Sylvian fissure was most enlarged (by 110%, $P < 0.001$) followed by the right Sylvian fissure (80%, $P < 0.01$), the frontal sulci (35%, $P < 0.05$), third ventricle (25%, $P < 0.05$), and VBR (18%, $P < 0.05$), whereas the parieto-occipital sulci and the fourth ventricle were not significantly altered.

(b) *Post mortem brains*: Volumes of several parts of the basal ganglia and limbic system of 14 schizophrenics and 10 controls collected before the introduction of neuroleptics were determined by planimetry of myelin-stained serial sections. The hippocampus (-20% , $P < 0.01$), amygdala (-15% , $P < 0.05$), parahippocampal gyrus (-30% , $P < 0.05$), pallidum internum (-15% , $P < 0.01$), and the diencephalic periventricular grey matter (-19% , $P < 0.01$) were smaller in the schizophrenic brains, whereas all parts of the striatum, the pallidum externum, and all large thalamic nuclei did not exhibit significant alterations.

There was no correlation between any of the data and the duration of the disease, thus, brain atrophy seems to exist before the onset of the disease. CT scans and post mortem brain measurements indicate that the anterior parts of the temporal lobe and the limbic structures within the temporal lobe are most affected in the brains of schizophrenic patients. Hippocampus and amygdala are anatomically and functionally interposed between neocortex and hypothalamus. Therefore, it is suggested that at least some clinical symptoms of schizophrenia are psychopathological equivalents of a functional dissociation between neocortical (cognitive) and hypothalamic (emotional) activities.

Neurofibrillary tangles are located in somatostatin neurones in Alzheimer's disease

Dr G. W. Roberts, Division of Psychiatry, Clinical Research Centre, Middlesex

Alzheimer's dementia is a chronic, progressive neuropsychiatric condition of unknown aetiology. It is characterised clinically by global intellectual impairment and neuropathologically by the presence of numerous argyrophilic plaques and tangles. Neurochemical investigations on post-mortem tissue have established losses of cortical cholinergic afferents and cortical somatostatin containing neurones. Other aminergic cortical projections systems are also affected although these are thought to be secondary changes. The transmitters of other intrinsic cortical systems are largely unaffected.

Immunocytochemical techniques and post-mortem tissue were used to examine the relationship of somatostatin immunoreactivity neuropathological markers. Somatostatin containing neurones exhibited morphological changes consistent with neuronal degeneration and marked decreases in somatostatin immunoreactivity were observed. Classical and immunological methods for demonstrating plaques and tangles showed an association of somatostatin with both. Further studies indicated that other neurotransmitters (VIP, CCK, Acetylcholine) were associated with plaque formation but not tangle formation. The findings indicate that somatostatin-positive neurones are degenerate and associated with tangle formation. Thus, destruction of somatostatin neurones is an early and perhaps critical event in the onset of Alzheimer's disease.

Anorexia nervosa

Gastric functions and anorexia nervosa

Professor P. R. McHugh, The Johns Hopkins Medical Institutions, Baltimore, USA

A steady growth in the understanding of gastric emptying has demonstrated that it is a biphasic phenomenon under strict control from the receiving intestine. Initially, the gas-

tric contents spill into the intestine which then regulates the subsequent flow of intragastric material according to its caloric content. Patients with anorexia nervosa and bulimia have been studied in both the starved and weight recovered state and several distinctions from normal are found amongst them that may have significance to their clinical state and management.

Schizophrenia—the nature of the disease process

The retrovirus/transposon hypothesis of psychosis

Dr T. J. Crow, Clinical Research Centre, Northwick Park Hospital, Middlesex

Twin and adoption studies suggest a genetic component in schizophrenia, but the extent of discordance in MZ twins is compatible with a role for an environmental factor. This could be a virus, and the findings in some family studies do not exclude horizontal transmission.¹

In pairs of siblings age of onset is significantly ($X^2 = 42.45$, $P < 0.0005$) more often younger in the younger sibling than would be expected from a 50:50 expectation. However this is due to ascertainment bias rather than contagion because the age shift is not seen in elder sibling ill first pairs. This observation excludes horizontal transmission and also environmental factors shared by the siblings and occurring at a defined point in adult life.

The hypothesis is proposed that psychosis is due to a pathogen integrated in the human genome which is acquired either from a parent or by an integration/transposition event occurring early in ontogeny. It is suggested that the pathogen integrates at the site of the gene (a 'proto-oncogene') which determines cerebral dominance. This could explain selectivity for the left hemisphere.

¹Crow, T. J. (1983) *Lancet*, i, 173–175

Aspects of the epidemiology of schizophrenia

Dr E. H. Hare, The Maudsley Hospital, London

It is still a matter of opinion whether the diagnosis of schizophrenia is sufficiently precise for its epidemiological study to be worthwhile. The speaker gives his reasons for thinking the precision is sufficient, and that epidemiological studies of schizophrenia have suggested causal hypotheses which are worth further study.

The most firmly established finding is the seasonal variation of admission rates for schizophrenia to psychiatric hospitals. Seasonal variation in the birth rate of schizophrenia patients is also firmly established and, if it is of aetiological significance, puts a severe constraint on the nature of the causal agents. Variations in incidence rate with place and time are less well established but raise the possibility that schizophrenia may be a relatively new disease, rare before the 19th century.

Is tardive dyskinesia a marker of 'organicity' in schizophrenia?

Drs T. R. E. Barnes and P. F. Liddle, Charing Cross and Westminster Medical School, London

Investigation of the characteristics of schizophrenic patients with tardive dyskinesia may identify risk factors for the development of tardive dyskinesia, and further the understanding of the nature and cause of certain schizophrenic symptoms in those patients who exhibit the

condition. The known risk factors for tardive dyskinesia are the administration of antipsychotic drugs, and increasing age, which probably reflects degenerative brain changes. The appearance of disorders of involuntary movement in schizophrenia, independent of drug treatment, raises the possibility that the schizophrenic disease process may also be a factor. It has been postulated that both the movement disorder and some of the disturbances of higher mental function seen in schizophrenia may be related to subcortical damage, such as lesions of the basal ganglia¹. This postulate is consistent with recent reports that schizophrenic patients with tardive dyskinesia show more signs of organic brain disorder. Compared with their non-dyskinetic fellows, such patients show more evidence of cognitive impairment as seen in early dementia, more 'soft' neurological signs, larger cerebral ventricles and an increased mortality. They are also more likely to develop other movement disorders, such as akathisia and tardive dystonia, and show a higher prevalence of 'negative' or 'type II' schizophrenic symptoms². One recent study also suggests that patients with 'non-familial' schizophrenia, where organic antecedents may have a larger role than in 'familial' schizophrenia, might be more likely to develop tardive dyskinesia³.

Dyskinesia in schizophrenia: relative contribution of neuroleptic treatment and the disease process

Drs J. L. Waddington, Hanafy A. Youssef, David J. King, Stephen J. Cooper, Department of Clinical Pharmacology, Royal College of Surgeons in Ireland, Dublin 2, St Davnet's Hospital, Monaghan, Ireland and Holywell Hospital, Antrim, N. Ireland

In agreement with previous studies, we have found schizophrenic patients who develop late-onset involuntary movements (IM, 'tardive' dyskinesia) to have received neither longer nor more vigorous treatment with neuroleptics in comparison with patients without orofacial IM. Rather we find them to be more likely to show negative symptoms and intellectual impairment.

In further studies, schizophrenic patients were assessed for IM using the AIMS and evaluated neuropsychologically for intellectual function; one patient group had been previously investigated by CT scan and ventricle-brain ratios (VBR) determined.

In an older population (age 30-90 y, n=68), both intellectual impairment and the prevalence of muteness increased significantly with age in patients with IM, while no relationship was present in patients without IM. In a younger population (age 25-67 y, n=16) VBR's were significantly larger in patients with IM; intellectual impairment increased significantly with age in patients with, but not in those without IM. VBR increased with both age and extent of intellectual impairment, but again only in patients with IM, similar relationships were found substituting duration of illness for age in these analyses.

Preliminary results of a stepwise logistic regression analysis, using data from 88 patients, identified the presence of

marked intellectual impairment of muteness as the factor best discriminating patients with IM from those without; their presence was also associated with the severity of such movements.

These studies point towards an association between the presence of involuntary movement and a distinct pattern of progressive clinical deterioration and structural brain changes in schizophrenia. This work was supported by the Medical Research Council of Ireland and the Royal College of Surgeons in Ireland.

Neurochemical laterality in schizophrenia

Dr G. P. Reynolds, Department of Pathology, University of Nottingham Medical School, Queen's Medical Centre, Nottingham

There is a substantial and increasing body of evidence indicating a hemispheric abnormality in schizophrenia. This has developed from the hypothesis of Flor-Henry who, on the basis of the occurrence of schizophreniform psychosis in left-sided temporal lobe epilepsy, proposed schizophrenia to be a dysfunction of the left temporal lobe. Studies involving evoked potentials, skin conductance, brain imaging, neuropsychology and, more recently, post-mortem anatomical investigations have all lent support to a lateral asymmetry of the brain in schizophrenia.

Despite the strong pharmacological indications of a dysfunction in dopamine neurotransmission, only one report has indicated a lateral asymmetry of dopamine function in schizophrenia. Dopamine, measured in post-mortem brain tissue from schizophrenic patients, was found to be significantly elevated in the left amygdala but not abnormally increased on the right. The neurochemical and regional specificity of this finding has been investigated further. No increase in a range of neurochemical markers for noradrenaline, acetylcholine, GABA, and serotonin neurotransmitter systems was observed in the amygdala. Dopamine showed no asymmetry in either the caudate or accumbens nuclei, although a lateral asymmetry in dopamine concentration paralleling that in the amygdala has also been observed in the temporal cortex.

While influences such as that of neuroleptic medication cannot be ruled out, these results certainly provide a neurochemical indication of a left temporal lobe abnormality in schizophrenia.

Short papers

A controlled trial of carbamazepine versus lithium in mania

Drs N. C. Moore, B. Lerer, E. Meyendorff, S. R. Cho and S. Gershon, Lafayette Clinic, Detroit, USA

Controlled comparisons with chlorpromazine and placebo have reported antimanic efficacy for the anticonvulsant carbamazepine (CBZ). Lithium (Li) has been conclusively demonstrated to alleviate manic symptoms and may thus serve as an ideal reference drug for evaluating antimanic efficacy. In the context of a double-blind trial, 34 consenting manic patients fulfilling DSM III criteria, were randomly assigned to treatment with CBZ or Li for four weeks. Treatment commenced with CBZ 600 mg/day or Li 900 mg/day and was increased to achieve serum levels of 9-12 mg/ml for CBZ and 1.0-1.5 mg/ml for Li. Serum levels were within the projected therapeutic range. Rating scales administered at baseline and weekly thereafter were: Brief

Psychiatric Rating Scale, Beigel-Murphy Scale and Clinical Global Inventory (CGI). Twenty-eight patients completed the full protocol, 14 on CBZ and 14 on Li. Analysis of the data by ANOVA with repeated measures showed a significant antimanic effect for both treatments on all three rating scales. The overall therapeutic response of the Li-treated patients was superior to that of CBZ but this difference did not reach statistical significance. There was, however, a significantly greater preponderance of good treatment responders in the Li group, whereas the overall CBZ effect depended on two excellent responders (CGI change score of 5 points) and two good responders (CGI change 2-3 points) in that group. These findings suggest that CBZ has antimanic potential in specific bipolar patients whose clinical characteristics remain to be clearly elucidated. Detailed results are presented.

Platelet 5-HT receptor binding in depression

Drs E. Charig, P. J. Cowen and Mrs S. Fraser, University Department of Psychiatry and MRC Unit of Clinical Pharmacology, Littlemore Hospital, Oxford

Changes in 5-hydroxytryptamine (5-HT) receptor sensitivity have been implicated in both depressive illness and therapeutic effects of tricyclic antidepressant treatment (TCA). The platelet possesses specific binding sites for lysergic acid diethylamide (LSD) which probably represent functionally active 5-HT₂ receptors.¹ We report the effects of depressive illness and TCA treatment on platelet LSD binding.

Venous blood samples were taken from depressed patients and healthy control subjects between 09.00 and 10.00 hours. The depressed patients met DSM-III criteria for major depression and had been free of all medication except benzodiazepines for at least three weeks. The binding of iodinated LSD to intact platelets was measured using a modification of a previously described method.¹ Platelet LSD binding did not differ between depressed subjects and controls. However, following four weeks' TCA treatment the number of platelet LSD binding sites was significantly increased. This study of platelet 5-HT receptor binding, therefore, does not support the hypothesis that 5-HT receptors are altered in depressive illness; however, it appears that TCA treatment may increase 5-HT₂ receptor density. This latter finding is at variance with what would be expected from animal studies but consistent with our previous report of increased LSD binding on the platelets of normal subjects treated with desmethylimipramine.²

Normal and abnormal variation in platelet 5HT transport: A comparison of control and depressed populations

Drs D. Healey, A. O'Halloran, P. A. Carney and B. E. Leonard, University College, Galway, Ireland

The original amine hypotheses of depression suggest deficiencies of central amines. Such hypotheses are inherently implausible. They were not supported by reliable clinical observations when first formulated and have since generated no reproducible clinical or biochemical evidence in their favour—with the single exception of platelet 5HT uptake which has been repeatedly reported to be lowered in psychotic depression. Such reports are of interest as many antidepressants purportedly inhibit 5HT uptake. There are

conflicting reports as to the effect of such agents on the lowered uptake of 5HT in depression.

We have investigated these issues further in a group of 28 psychotically depressed patients. Some of the group were treated with uptake inhibitors and the rest by other means. Uptake was measured at several points during the day and during the illness.

Our findings confirm reports of an abnormality in platelet 5HT transport but do not support the notion of amine deficiency or indeed of a primary aminergic abnormality. Other possible explanations are offered.

The predominant hypotheses concerning the psychological abnormalities in depression propose alterations in cerebral biogenic amine concentrations or functioning. Platelet 5-HT reuptake has been shown to be reduced in depression and is one of the few pieces of evidence from depressed persons, which has been consistently reproduced, that can be cited in favour of these hypotheses. In this study, platelet 5-HT reuptake was measured at three time points during the morning in depressed persons, before treatment, acutely after its institution and following chronic administration, and compared to controls. Control rates varied in a manner consistent with the presence of a circadian rhythm in uptake. Depressed persons showed no variation at these times of measurement. Clinical recovery was accompanied by a restoration of variation. This normalisation was not found after acute administration of antidepressants or ECT and was independent of the effect of treatment on the affinity of the transport system. These results are consistent with the notion that the pathophysiology of depression involves a disruption of circadian rhythms, yielding secondary abnormalities of biogenic amines rather than a primary monoaminergic disturbance. Among the depressed persons studied, those who were deluded displayed a qualitatively similar profile of uptake rates to the other depressed subjects but had quantitatively different rates at each time point.

This finding may be pertinent to the clinical experience that when depression is accompanied by delusions its response to treatment differs from that of depressions without delusions.

Is lithium justified after one manic episode?

Dr A. J. Mander, University of Edinburgh

A retrospective survey of first admissions with a diagnosis of mania revealed that almost half the patients concerned were discharged on prophylactic lithium. The decision to use lithium was influenced by a number of factors including severity and duration of illness, sex and social class. A follow-up study revealed that none of these factors, nor any others examined predicted outcome.

Although lithium was shown to be an effective prophylactic, the outcome of those treated with it was not significantly different from the untreated group. The reasons for this are discussed and some tentative evidence of a lithium withdrawal state presented.

Which depressives have blunted growth hormone responses to clonidine

Drs C. L. E. Katona, A. S. Hale, A. E. Theodorus, S. L. Davies, C. Tunnicliffe, R. W. Horton, E. S. Paykel and J. S. Kelly, St George's Hospital Medical School, London

Growth hormone (GH) response to the selective α_2 adrenoceptor agonist clonidine has been reported in several studies

to be blunted in depression.^{1,2} Our own preliminary report³ suggested that although there was no obvious blunting of GH responses in depressives overall, a subgroup showing dexamethasone suppression test (DST) non-suppression had significantly blunted responses. We report our investigation of the inter-relationships between the GH response following 1.3 ug/kg clonidine, the 1 mg, single sample DST, and a number of clinical variables in 41 depressed subjects with RDC major depressive disorder and a minimum Hamilton Depression Rating (HDRS) of 17. Our results are as follows:

Table I
Correlations with GH response (area under curve)

	Spearman's rho	P
Post Dexamethasone Cortisol (ug/100 ml)	-0.52	<0.01
Age (years)	-0.27	<0.1
Hamilton Depression Score	-0.02	NS
Drug-free Interval (days)	-0.15	NS
Feinberg-Carroll Score	0.07	NS
Newcastle Score	-0.10	NS

There is a highly significant correlation between post dexamethasone cortisol (PDC) and GH response; DST non-suppressors (n=17) as a group show significantly smaller GH response than suppressors (n=16; U=61.5; P=0.01) suggesting a negative relationship between GH response and age. PDC also correlates highly significantly with age (rho=0.4, P<0.01) but the PDC/GH response relationship remains significant after the effect of age is partialled out (rho=0.33, P=0.05). Neither severity of depression nor drug-free interval prior to testing correlate significantly with GH response or PDC. Of our measures of endogeneity, neither the Newcastle scale nor the Feinberg-Carroll discriminant index correlate with GH response or PDC. RDC definite endogenous depressives (n=32) however show a just significantly lower GH response than RDC probable and non-endogenous depressives (n=9; UO=90, P<0.05, 1-tailed) We conclude that a common neurochemical mechanism may be responsible both for blunting of the GH response to clonidine and of the cortisol response to dexamethasone in depression.

Genetic markers in late paraphrenia—A study of HLA antigens

Drs M. Naguib, P. McGuffin, R. Levy, H. Festerstein and A. Alonzo, *The Maudsley Hospital, London*

Thirty-one unrelated British patients with late paraphrenia were typed for HLA-A, -B, and -C. Increased frequencies of BW55 (P=0.036, relative risk 4.05), B37 (P=0.008, relative risk 4.34) and CW6 (P=0.056, relative risk 2.24) were found relative to controls. Unlike findings in paranoid schizophrenia there was no HAL-A9 association. This suggests that patients with paraphrenia may be biologically and genetically distinct from schizophrenics. No significant negative association was found with any of the HLA anti-

gens tested. Although the association found does not remain significant after correction for the number of antigens tested, the primary association seems to be with B37 which, despite occurring only in a minority of patients, shows the lowest corrected P value and highest relative risks. If the HLA-B37 association is confirmed in a new study it would make possession of this antigen a strong risk factor for developing the disorder.

Acute and tardive akathisia

Drs T. R. E. Barnes and W. M. Braude, *Horton Hospital, Surrey*

In a recent study¹ of consecutive acute psychiatric admissions receiving antipsychotic medication, acute akathisia developed in 25% as a strongly dose-related phenomenon. The signs and symptoms of mild, moderate and severe drug-induced akathisia were elaborated, and allowed distinction from agitation and restlessness associated with psychiatric illness. The relationship between akathisia, parkinsonism and response to anticholinergic agents was examined. In the majority of patients there was no association between akathisia and severity of parkinsonism, and anticholinergics were relatively ineffective. In the small group of patients with severe parkinsonism, akathisia was invariably present, and in this context both the akathisia and parkinsonism responded to anticholinergic treatment.

Diagnostic criteria for acute akathisia were derived, and applied in a sample of established schizophrenic outpatients.² Previous work³ had suggested that akathisia and oro-facial tardive dyskinesia commonly coexisted in such patients, and this finding was confirmed. A group of patients with 'chronic' akathisia were identified, which included cases with acute akathisia which had persisted, as well as cases of 'tardive' akathisia. This tardive akathisia variant is characterised by a late-onset, an association with oro-facial and trunk and limb dyskinesia, in that the condition appears or worsens on drug dose reduction or withdrawal, and tends to improve when the dose is increased.⁴

Screening for alcohol problems in a non-clinical setting

Dr J. Spencer, *Director of Clinical Services, W. A. Alcohol and Drug Authority, Salvatori House, 1st Floor 35 Outram Street, West Perth, WA 6005*

With the realisation that early intervention and treatment carries a better prognosis, agencies face the problem of detection and referral of such patients. The problems of social norms and denial are of particular significance in offering help to those with drinking problems.

In an attempt to overcome these obstacles, the local Alcohol and Drug Authority has been using mobile alcohol screening and display units in suburban shopping centres. Included in these displays have been computerised terminals incorporating simple alcohol knowledge questions and the CAGE and SMAST questionnaires. The results indicate

that over 30% of respondents were drinking pathological amounts of alcohol and that many were doing so in ignorance of what is regarded as safe levels of drinking. There was a significant correlation between the CAGE and SMAST questionnaires thus confirming their validity in such community surveys. The paper discusses some of these issues and results.

A study of deliberate self-poisoning in the accident and emergency department

Dr D. W. Owens and Mr S. J. Jones, University Hospital, Nottingham

It is acknowledged that many accident and emergency departments do not admit all the patients presenting with deliberate self-poisoning. Little is known about such screening procedures and this study was carried out to quantify and make some evaluations of the practice in one department.

Every patient attending the Nottingham accident and emergency department over a four-month period in early summer 1982 with the presenting complaint of overdose was identified retrospectively. The case-notes of all 525 patients were examined for demographic data, drugs and alcohol taken and the initial management of the case. The Nottingham Psychiatric Case Register was examined to provide information about previous psychiatric contacts and use of psychiatric services over a two year follow-up period.

The study shows statistically significant differences between those patients admitted to a ward and those who return home from A & E, in respect of likelihood of psychiatric morbidity and use of psychiatric services. The results suggest that whilst one in three self-poisoning patients returns home directly from the accident department, there is some degree of appropriate selection in that department regarding factors of psychiatric importance.

Application of dexamethasone suppression test in dementia

Drs M. T. Abou-Saleh, E. M. Spalding and J. M. Kellett, Department of Psychiatry, St. George's Hospital, London and Dr A. Coppen, MRC Neuropsychiatry Laboratory, West Park Hospital, Surrey

The performance of the Dexamethasone Suppression Test (DST) was investigated in 60 demented patients including 14 patients admitted to a psychogeriatric assessment ward, 29 electively admitted patients and 17 long-stay patients in comparison with 37 middle-aged and elderly controls. It was shown that acutely admitted patients had the highest rate of DST non-suppression (86%), whilst electively admitted patients had a lower rate (55%), in comparison with long-stay admissions (65%), and controls (11%). In the electively admitted group abnormal DST results were associated with weight loss and depressive symptoms. There was no association between DST results and cognitive, behavioural and cortical dysfunction, including degree of cerebral atrophy as determined by CT scan. It is suggested that abnormal DST response reflects a biological dysfunction that cuts across the clinically established boundaries of psychiatric nosology and indicates a versatile component in psychiatric disturbance that could serve to predict or monitor the effects of physical and psychological intervention.

Poster presentations

Therapeutic factors in bulimia nervosa

Dr U. Schmidt, The Maudsley Hospital, London

The purpose of this study was to examine the usefulness of therapist-aided cue exposure to sight, smell and taste of food in the treatment of bulimic patients. Binge-eating was construed as an avoidance behaviour that helps the individual to reduce or avoid unpleasant moods (such as boredom, anxiety, and the discomfort or conflict produced by the desire to eat 'forbidden' foods). It was postulated that in binge-eating as in other avoidance behaviours cue exposure to food should result in response decrement (of the urge to binge). Four patients who fulfilled Fairburn's and Cooper's (1984) operational criteria of bulimia nervosa were each given 12 sessions of cue exposure to food. A single-case multiple-baseline strategy was used, with in-session and between-session measures. Three out of the four patients showed moderate to marked improvement at one-month follow-up which in two cases was maintained at six-month follow-up; one patient had partially relapsed. The fourth patient dropped out of treatment after nine sessions. Two of the improved cases showed in-session habituation and some degree of across-session habituation. The patient who dropped out showed within-session habituation but no between-session improvement.

The results of this small study are preliminary evidence that cue exposure to food might be a useful adjuvant in the treatment of bulimia nervosa.

The effect of a nurses' strike on the psychiatric care provision of a mental hospital

Drs M. Abdelkader, Hollymoor Hospital, Birmingham, J. Kogeorgos, Horton Hospital, Epsom and P. Fonagy, University College, London

Mental hospitals have been traditionally the main place of treatment for the psychiatrically ill, but in the past few years, their role has been questioned and there are current plans to close a substantial number of them.

We had the opportunity of evaluating the importance and pattern of psychiatric care provision of a mental hospital (Horton Hospital) during a six-month period in which this provision was drastically curtailed by industrial action of the nursing staff. The clinical, social and demographic characteristics of all patients admitted during this period (112) were analysed and compared with those of patients admitted during the corresponding period of the previous year.

In the study period the number of informal patients admitted dropped by 50%, but this was partly related to admission policies. The number of compulsory admissions remained the same but patients were admitted predominantly under emergency sections (Section 4 and 2) rather than Sections 136 and 37 as in the control period. A proportion of the compulsorily admitted patients in the study period would have normally come in informally and there was a significant overall excess of patients with a history of an organic psychosis and patients who had not been professionally supervised in the community.

We discuss the significance of our findings in relation to current government attitude and policies for future mental health care provision.

Multiple sclerosis: A correlative investigation of psychiatric, neurological and psychological impairment

Dr J. Kogeorgos, Horton Hospital, Epsom, Mr R. Brown, North London Polytechnic and Mr C. Kennard, The London Hospital

Mental changes are a well recognised feature of multiple sclerosis (MS) and have been intensively studied, but their exact nature and pathogenesis remain unclear. This reflects the complexity of the disease and related methodological difficulties, notably the restricted and often uni-dimensional approach adopted in many previous studies.

We present preliminary findings from a collaborative investigation of 82 patients (53 females, 29 males; age range 20–60; mean 35 years), with 'definite' MS by McAlpine's criteria. These patients were free from other major organic problems or psychiatric history prior to the onset of their MS and were selected consecutively from the chronic patients attending a busy neurological out-patient clinic. Their assessment consisted of systematic psychiatric (Goldberg's Standardised Interview and Beck's Short Depression Inventory), neurological and psychological evaluation, combined with objective investigation of cerebral function (computerised tomography of the brain, EEG and Visual Evoked Potential recordings), all tests on each patient being completed within a week. The results were analysed to identify relationships between these and other clinical variables including age, sex type and length of illness, and were compared with those from a control group of other chronic neurological out-patients of similar overall range of disability.

Both groups were cognitively impaired but the MS patients showed significantly greater psychiatric disturbance. However, this was non-specific and consisted mainly of affective changes especially depression, as well as irritability and a feeling of excessive fatigue. The psychiatric morbidity present showed little relationship to either physical or intellectual impairment.

An analysis of the elderly in a general psychiatric hospital

Dr S. M. Rea, Tyrone and Fermanagh Hospital, Northern Ireland

A cross-sectional survey assessed all elderly patients in a general psychiatric hospital in Co Londonderry, Northern Ireland. They comprised 42% of the total hospital population. The unusual finding of an almost equal number of male and female patients is discussed.

The cohort was divided into 'new long-stay' (22%) and 'old long-stay' (60%) as defined by Wing (1980). The majority of 'new long-stay' patients had a diagnosis of dementia while the majority of 'old long-stay' patients had a diagnosis of schizophrenia.

The Behaviour Rating Scale (BRS) of the Clifton Assessment Procedures for the Elderly (CAPE) (Pattie & Gilleard) was used to measure the 'level of dependency' of all elderly patients. A high degree of dependency was found in 60%. Only seven patients who did not have a diagnosis of dementia, and who had been in hospital less than five years, were identified in the continuing care wards as potentially suitable for a more independent existence outside hospital.

The Information/Orientation subtest of the CAPE revealed that the majority of non-organic patients also had very poor orientation scores. A more detailed analysis of the BRS estimated the degree of apathy and socially disturbed behaviour within the three main diagnostic groups.

These findings which confirm that the elderly in a psychiatric hospital are a severely handicapped group, have major implications in the development of the most suitable ward milieu and in the organisation of a psychogeriatric service. Government policy to replace large mental hospitals and the development of alternative care for the elderly in the community are also discussed.

Lesion size and outcome following stereotactic subcaudate tractotomy

Drs A. S. Hale, J. Bartlett and P. K. Bridges, Geoffrey Knight Psychosurgical Unit, London

Stereotactic subcaudate tractotomy (SST) is a psychosurgical technique for the relief of intractable depression which has been carried out in Britain since the mid 1960s.¹ Although the clinical effectiveness of the operation has been generally accepted,² it has not been possible to perform an adequate or ethically acceptable, double blind, or even open, controlled trial. Apart from anecdotal evidence from early work¹ there has been no examination of the effect of varying lesion size on outcome. The mechanism of action of SST is thought to involve the severing of projection fibres from the limbic system to the frontal cortex. There should thus be an optimal size for the lesion.

We report a prospective, double blind, non-controlled study of the effect on outcome of varying lesion size. The number of Yttrium 90 rods used thus varied, irradiating a range of volumes of brain. Both patient and assessor were blind to the number of rods used. This study is as near to the needed double blind controlled study as is ever likely to take place. Two hundred and fifty nine consecutive cases of intractable depression were given one of four lesion sizes on a cohort basis. 12, 16, 20 or 24 rods were used. Outcome was assessed blind to varying lesion size, one year after SST. Outcome was defined as: 1. Asymptomatic. 2. Well, mild residual symptoms. 3. Improved, significant symptoms remain. 4. Unchanged. 5. Worse. Results are shown in Table 1.

Table 1
Numbers of patients in each outcome group with varying Y90 rod number

		Number of rods			
		12	16	20	24
Outcome Category	1	11	6	14	1
	2	30	10	29	2
	3	36	16	21	2
	4&5	31	17	29	4

There is a sex difference in lesion size effect on outcome. For males, the optimal size was 20 rods, showing significantly more improvement than 16 rods ($P=0.01$), which in turn was significantly better than 12 rods ($P=0.04$). For females, this effect was weaker, only the 12 v 20 rod comparisons being significant ($P=0.04$). There was no significant relationship between age and outcome. Outcome was poorer in the small 24 rod group, this lesion size being abandoned because of frequent post operative confusion. The optimal lesion size was thus 20 rods. The data provides supportive

POSTER PRESENTATIONS

evidence for the effect of SST being directly related to the production of the subcaudate lesion.

¹KNIGHT, G. J. (1965) *Journal of Neurology, Neurosurgery and Psychiatry*, **28**, 304-310

Prognostic factors and outcome after 20 years in anorexia nervosa

Dr R. H. Ratnasuriya, The Maudsley Hospital, London

Forty one patients admitted to the Metabolic unit Maudsley Hospital, consecutively between 1959 and 1966, were followed up. The mean time of follow up from admission was 20 years. Information was gathered on 23 patients (56.1%) by personal interview, one patient (2.4%) by telephone interview which was confirmed by mother, on six by postal questionnaire, on four from GP. Seven patients were dead. One patient who was living abroad did not respond.

Outcome was assessed on weight gain and menstrual function and socioeconomic functioning. A retrospective case note study was also done to find prognostic factors related to outcome.

29.3% had a good outcome, 31.7% an intermediate outcome and 19.5% had a poor outcome. 17.1% were dead. Neurotic traits, personality problems, disturbed relationships in the family, age of onset of illness, length of illness on admission, age on admission and maximum weight gained in hospital were significantly related to outcome. Other factors mentioned in the literature were not found to be significant. These results and their relationship to the results of a five year follow-up study of the same group of patients are discussed.

Sub-acute limbic encephalitis

Dr J. A. N. Corsellis, Runwell Hospital, Essex

The limbic areas of the brain have long held a particular fascination for those interested in organic psychiatry. Although they are reasonably well-defined within the medial depths of the cerebral hemisphere, few pathological conditions are well-enough confined to them to justify even primitive attempts to establish clinical and neuropathological correlations. One exception may be the way in which at least certain parts of the limbic grey matter become involved in a curiously selective, and fortunately rare, form of encephalitis (or encephalopathy) which has a close, but by no means, inevitable association with carcinoma, usually of the lung.

The present paper tries to outline the ways in which the condition has come to be recognised as one of the lesser known causes of marked intellectual impairment, possibly dementia, and perhaps most striking of all, a marked disturbance of recent memory.

The clinical and the neuropathological features of the disorder are summarised and the latter illustrated. Some of the questions raised by the nature and the localisation of the pathological process are raised.

The nature of chronic schizophrenia

Dr Eve C. Johnstone, Northwick Park Hospital and Clinical Research Centre, Middlesex

This paper is a summary of Northwick Park studies of schizophrenia which do not concern acute episodes. A survey of 510 in-patients with chronic schizophrenia showed widespread severe abnormalities which were not associated with past physical treatment but were significantly related to duration of illness/hospitalisation. Subsequent studies comparing this population with a sample of discharged schizophrenic patients and one of institutionalised manic depressives showed closer similarities between the two schizophrenic groups than between the two groups of in-patients. It was concluded that schizophrenia was frequently associated with serious defect and that this did not depend upon environmental circumstances. The degree of defect is highly variable and studies of the structure of the brain and of anterior pituitary function, while showing abnormalities in chronic schizophrenia, do not provide clear cut correlates with clinical state. Recent studies of early outcome indicate that severe and early defect is still commonplace. The influence of treatment upon this is discussed.

In vitro and in vivo studies of dopamine receptors

Dr F. Owen, Division of Psychiatry, Clinical Research Centre, Middlesex

Neurochemical studies in post-mortem brain material from schizophrenics have failed to provide any evidence for increased dopamine turnover in the central nervous system. However, there have been a number of reports of increased dopamine D² receptors in brains from schizophrenics compared with controls. It remains unclear whether or not this increase in D² receptors is entirely due to the effects of neuroleptic medication. More recently attention focused on assessing D² receptors in living subjects. Spiperone can be brominated at the para position on the benzene ring to produce parabromospiperone which retains its neuroleptic activity and D² ligand binding characteristics. When 77 bromine is used as the bromine source 77Br-bromospiperone (77 Br-BrSp) is produced which is a gamma emitter with a half-life of 56 hours and hence is suitable for clinical studies.

With 77Br-BrSp as ligand good computer reconstructed images of the radioactivity in human brain have been obtained using the IGE 400T gamma camera with a star computer system. When the technique was used to assess D² receptors in drug-free schizophrenic patients a small but significant increase, compared with controls, was obtained.

Winter Quarterly Meeting, 1986

*The Royal Society, 6 Carlton House Terrace, London SW1
(21–22 January 1986)*

Surveys of the development of psychiatric services for old people

Dr J. P. Wattis, St James's University Hospital, Leeds

Specialised psychiatric services for old people have grown rapidly over the last 15 years. This fact has been invisible in national statistics because psychiatry of the elderly is not treated as a subspeciality for statistical purposes. Three surveys have been undertaken to define this major new area of psychiatry. The first, in 1980, found 106 specialist consultants (though the real total was estimated to be around 120). Over half the respondents had started to work in the field in the preceding five years.

By 1983 there were at least 150 consultants working predominantly with old people though recruiting was depressed by a shortage of suitable senior registrar training posts. There were more services with more than one consultant and proportionately more full time appointments. The current survey expects to find 200 or more consultants in the field.

The studies have also examined staffing and facilities, and a synopsis of results is presented. The relationship of old age psychiatry to general psychiatry is also explored.

What should liaison psychiatry be doing?

Dr R. Mayou, University Department of Psychiatry, Warneford Hospital, Oxford

In North America, liaison psychiatry has rapidly become a sub-speciality which claims an expanding role in the psychiatric care of general hospital attenders, in training psychiatrists, and in teaching other professional groups. There has also been increasing interest in Britain, but services are poorly organised and usually provided by general adult or child psychiatrists, who feel that they have too little time to provide a satisfactory clinical service.

Review of the prevalence of psychiatric morbidity in general hospitals shows that it is common as (a) a response to physical illness, (b) psychiatric disorder presenting with physical complications (deliberate self-harm, alcohol, eating disorders), (c) hypochondriacal somatic symptoms. Many of these problems are unrecognised by physicians and surgeons and even when recognised, it is uncertain that they are adequately treated. Although much of the psychiatric disorder seen in the general hospital does not require specialist care, it is apparent that major problems are not being treated and that these cause considerable distress for patients and families, and limit the effectiveness of medical treatment.

Psychiatric liaison teams are only able to see a very small proportion of the general hospital patients. Although hospital doctors, nurses and other members of the clinical teams must continue to be responsible for the major part of psychological care, it is uncertain whether they have the necessary skills. The liaison psychiatry team has an important role in providing a well-organised emergency and consultation service and should, in addition, attempt liaison links with those general hospital units which have a particularly high prevalence of major psychiatric problems. Liaison psychiatry should be a part of every training programme for general and child psychiatry.

Alcoholic dementia

Professor W. A. Lishman, Institute of Psychiatry, London

The problematical concept of alcoholic dementia is discussed with emphasis on its uncertain nosological status. The lines of evidence which have a bearing upon it—all inconclusive of themselves—are presented, including recent evidence from psychometry and CT scanning. Possible pathogenic mechanisms are for discussion.

Can schizophrenia be localised in the brain?

Professor N. C. Andreasen, Department of Psychiatry, University of Iowa, USA

This presentation reviews several lines of evidence concerning the localisation of brain abnormalities in schizophrenia. It discusses hypotheses concerning diffuse versus specific localisation. Evidence based on CT scanning, BEAM, NMR, PET, regional blood flow, and neuropathological studies is reviewed. The preponderance of evidence appears to suggest a specific rather than diffuse localization. The specific site has not been identified, and in fact multiple sites may be involved.

Eli Lilly lecture: Mindlessness and brainlessness in psychiatry

Professor Leon Eisenberg, Harvard Medical School, Boston, USA

Brain and mind are as warp and woof to the fabric of psychiatry. Yet, psychiatric theories have tended to be, as with psychoanalysis, 'brainless' or, as with biological psychiatry, 'mindless'. The sources of this polarisation are explicated by the history of our speciality. Nonetheless, an informed review of the phenomenology of psychiatric disorders makes evident the inadequacy of unitary formulations.

Exclusively biological and psychological theories in psychiatry stand in relation to one another much as wave and particle theory do in subatomic physics. Both formulations are necessary to account for the universe of observation. The unique role of psychiatry in medicine lies in the extent to which it contributes to an understanding of the ways in which the mind is embodied and the body literally mindful. However far we may be from that goal, the striving for it is the *raison d'être* of our speciality.

Behavioural psychotherapy in general practice

Professor I. Marks, Institute of Psychiatry, London

Behavioural psychotherapy can often be given as successfully by general psychiatrists as by specialists. Clinicians need to delineate the clinical features of the problem, know when behavioural methods are applicable and their principles. Most behavioural approaches involve self-treatment by the patient with the clinician acting as guide and monitor. Using a suitable manual and diary, agoraphobics, social phobics and specific phobics improved as much with self-exposure by following a manual and keeping an appropriate diary as others who were given exposure instructions by a psychiatrist. Therapist-aided exposure added little to self-exposure + self-imposed response prevention for compulsive ritualisers, both approaches producing satisfactory gains. Much sexual dysfunction can also

be helped by general psychiatrists with simple instructions and monitoring. Anxiety and conduct disorders in children have also responded to simple guidance, as has enuresis. Specialist behavioural treatment is only indicated if behavioural guidance by general psychiatrists has failed.

Recent advances in prophylactic lithium treatment

Professor M. Schou, Aarhus University Institute of Psychiatry, Denmark

Now that the fear of progressive kidney damage during long-term, lithium treatment has been allayed, attention may be focused on appropriate information and instruction of patients, ongoing psychological support, clinical and laboratory monitoring, choice of optimal serum lithium concentration for maximum of benefit and minimum of side-effects, avoidance of situations involving risk of lithium intoxication, early detection and proper treatment of lithium intoxication, the significance of salt and water deficiency, interaction with other drugs, and course of action in case of incomplete or lacking response.

Patients who attribute their psychiatric symptoms to food allergy

Dr K. J. B. Rix, St James's University Hospital, Leeds

Wide publicity is being given to unsubstantiated claims that food allergy is responsible for all sorts of conditions in addition to the classical atopic diseases of asthma, eczema, urticaria and gastrointestinal food hypersensitivity. However, the most common reason for failing to tolerate foods is psychological and most patients with supposed food allergy present with psychiatric symptoms.

Although many lay people use the term 'allergy' to refer to any negative reaction to a substance and some professional groups apply it to all idiosyncratic or acquired adverse reactions, the term should be restricted to immunologically-mediated adverse reactions.

This lecture discusses the differential diagnosis of patients with supposed food allergy presenting to the adult psychiatrist. It encompasses distaste, food fads, food phobia, anorexia nervosa, organic hypersensitivity (including food allergy), psychological hypersensitivity and normal reactions to toxins and pharmacological agents. The diagnosis should only be reached after appropriate history-taking, examination, and, in some cases, dietary investigations, double-blind food challenges and immunological tests

Unorthodox investigations and treatments are mentioned.

Violence and psychosis: offenders and patients

Dr P. Taylor, Institute of Psychiatry, London

The best calculated estimates of risk suggest that only a very small proportion of psychotics become seriously violent. Nevertheless large numbers of them appear in prisons and their rate of violent offending is probably increasing. Violence is a key reason for admission to hospital for a substantial minority.

Reports differ in the importance they attach to the psychotic process as a precipitant of violence. Those based on prison samples tend to show the illness as less relevant compared with those based on hospital samples. In the only

large interviewed sample of psychotic offenders all but 7% were actively symptomatic at the time of their offence and nearly 50% had probably been driven by their delusions or hallucinations. Only 10% of this series were newly identified cases. Other work confirms that serious violence is rarely a presenting feature of the illness. Is violence by psychotics thus chiefly a manifestation of the failure of psychiatry and supporting services? Among men remanded to prison for a range of offences, 71% of schizophrenics, the majority of whom were said to be actively ill, failed to find a hospital disposal.

Psychiatric aspects of Parkinson's disease

Dr G. E. Berrios, University of Cambridge

A short historical incursion, showing that Parkinson did not mean to exclude 'psychiatric' disorder from his definition of the disease is followed by a discussion of some of the methodological difficulties affecting research in this area.

Preliminary results from the Addenbrooke's Study (based on 58 subjects under 70) are presented. Exploratory factor analysis extracted four factors: depression, cognition, illness/treatment and motor status. Hypotheses therein suggested were tested internally or by carrying out additional subprojects.

The following conclusions are drawn: 1. Evidence for affective and cognitive disorder can be found in a sample of PD sufferers under 70. 2. These disorders are not clinically coterminous with 'major depression' or 'dementia', respectively, as conventionally defined. 3. High doses of Ach compounds predict low free recall and affect the 'A' value in a signal detection task. 4. There is no correlation between severity of motor and affective disorder. 5. There is no correlation between severity of motor and cognitive disorder. 6. In general, motor symptoms have (apart from rigidity) low predictive value with regards to mental disorder. 7. PD subjects exhibit no conservative bias in a signal detection task but show memory impairment. 8. PD subjects show no frontal lobe involvement as defined by a verbal fluency task. 9. The Addenbrooke's Scale offers some advantage in the assessment of depression in the PD patient. 10. Longitudinal studies of PD cohorts are recommended. 11. Clinical and instrumental identification of primary neuropsychological abnormalities should help distinguish phenocopies from real psychiatric syndromes.

Life events and the onset of illness

Dr F. Creed, Manchester Royal Infirmary

Life events are clearly related to the onset of psychiatric illness and the relevant vulnerability factors are becoming better defined. The relationship of life events and the onset of physical illness is less clear and the vulnerability factors involved have yet to be elucidated.

Studies of life events and the onset of illness affecting the gastro-intestinal tract suggest that a different type of event may be related to the onset of definite organic disease than the onset of non-organic gastro-intestinal disorder. In the latter case the type of life event has similarities with those preceding deliberate self-poisoning. Some intervening variables between life event and somatic illness are suggested.

Spring Quarterly Meeting, 1986

Manchester (15-16 April 1986)

Dementia

Ultrastructural studies in Alzheimer's disease

Dr D. M. A. Mann, University of Manchester

Ultrastructural (electron microscope) studies in Alzheimer's disease have to date concentrated on four aspects of pathology. (a) ultrastructural characterisations of senile plaques, neurofibrillary tangles and Hirano bodies; (b) cytological changes in nerve cells in relationship to neurofibrillary degeneration, (c) synaptic alterations; and (d) aetiological factors.

Senile plaques are thought to evolve through several pathological stages. They start out as primitive plaques consisting of clusters of dystrophic neurites, mature into classical plaques with amyloid core, astrocytic processes and many neurites and finally regress into burnt out plaques in which the neuronal elements are lost. Tangles comprise of sheafs of paired filaments, each of 10 nm diameter wound helically at a periodicity of 150 nm. Hirano bodies are paracrystalline arrays of filaments thought to comprise of actin.

Accumulation of neurofibrillary material in cortical pyramidal cells is associated with progressive reductions in the amount of useful cell cytoplasm, the size of the nucleus, the amount of rough endoplasmic reticulum and the number of ribosomes. Mitochondria are unaltered and lipofuscin is increased. Cells unaffected by tangle are unchanged in these respects. The protein synthetic capacity of nerve cells is thus diminished with accumulation of tangle; neurofibrillary degeneration may be the major cause of nerve cell loss in Alzheimer's disease.

Loss of synapses from temporal cortex averages over 50%, whereas neuronal perikaryal loss averages 30%; synapse to neurone ratio is therefore decreased by 33% in Alzheimer's disease, suggesting a primary, or at least a preferential, destruction of nerve terminals.

Electron microscope observations in Alzheimer's disease have identified various 'organelles' within nerve cells or neuropil, possibly indicative of pathological change relevant to the aetiology of the condition.

Selective cortical neuronal degeneration in Alzheimer-type dementia

Dr A. J. Cross, Department of Physiology, University of Manchester

Neurochemical studies on the post-mortem brains of patients with Alzheimer-type dementia (ATD) have described a marked loss of markers of cholinergic terminals in the cortex and limbic lobe, which correlates with the extent of clinical and pathological severity of the disease. Deficits have also been described in other ascending neurones, particularly those containing serotonin and noradrenaline. The loss of terminals of these ascending neurones cannot account for the extent of cortical degeneration present in ATD, and recent evidence suggests that these ascending neurones degenerate in a retrograde fashion.

A number of markers of intrinsic cortical neurones

have been studied in ATD. Of these it appears likely that somatostatin concentrations and serotonin S2 receptors are reduced in ATD, possibly reflecting a loss of a subset of cortical neurones. In addition, high-affinity glutamate uptake sites are reduced in ATD. The glutamate uptake site is a marker of neurones using glutamate as transmitter and includes cortico-cortical (association) neurones and corticofugal neurones. The relationship of these changes to the pathogenesis of the disease will be discussed.

Brain imaging techniques in the evaluation of dementia

Dr J. A. O. Besson, Department of Mental Health, University of Aberdeen

Two brain imaging techniques that have relevance in the clinical study of dementing conditions are nuclear magnetic resonance (NMR) imaging and single photon emission tomography (SPET).

NMR imaging involves the pictorial reconstruction of data derived from the behaviour of mobile H nuclei following excitation by magnetic forces. These magnetic forces are applied in the form of a series of pulses in different directions (90° or 180°) from the main magnetic field in which the subject is situated. The Aberdeen imaging system is based on an intercalated saturation recovery (90° pulse) inversion recovery (90° pulse preceded 200 ms before by an 180° pulse) sequence but other types of pulse sequences are possible.¹ Three types of data can be obtained by this method: proton density (PD), inversion recovery (IR), and spin lattice relaxation time (T). Images based on these data can be obtained for each section and transverse, coronal, and sagittal displays are possible.

In SPET the distribution of a gamma-emitting radio-labelled compound in an organ following intravenous injection is imaged by a camera made up of a series of gamma radiation detectors. The technique described in the current study images regional cerebral blood flow (rCBF) by detecting the distribution of 123 labelled *n*-isopropylmethylamphetamines (IMP),² which is taken up by the tissue on first pass through the brain following intravenous injection.

Diagnostic criteria based on DSM-III were used; patient groups studied were Alzheimer's disease (ATD), multi-infarct dementia (MID), Parkinson's disease with and without dementia, Korsakoff psychosis, alcoholic cortical atrophy (ACA) and Huntington's chorea. Hachinski ischaemic score was applied to the separation of ATD and MID groups. Age-matched normal controls were studied.

Changes observed in dementia using NMR are cortical atrophy and ventricular change (PD mode—best), periventricular white matter change (PVC) (increased T and IR, no change in PD), recent infarct (increased T and IR, no change in PD), old cystic infarct (increased T and IR and reduced PD), old gliotic infarct (normal T and increased PD).³ These changes may be quantified.⁴

In ATD, 50% of patients have elevated T lesions in the posterior watershed white matter areas on NMR⁵ and 90% of patients have bilateral reduction in cerebral blood

flow in the posterior perietal grey on IMP compared with none of the controls.⁶ In MID, 75% of patients had infarcts, PVC, or both together on NMR, and 100% of patients had focal or marked generalised reduction in rCBF on IMP, compared with none of the controls.

In ACA, cerebral atrophy only was seen on NMR and generally irregular radionuclide uptake on IMP, predominantly frontal. In pure Korsakoff psychosis NMR and rCBF appearances are normal, but where coexisting alcoholic cortical atrophy is present, predominantly frontal reduction in rCBF can be identified.

In Huntington's chorea increased intercaudate width and reduced volume of the head of the caudate can be seen, but no measurable change in T on NMR. Those with dementia do not show reduction in rCBF on IMP. Patients with depressive pseudodementia do not show abnormalities on rCBF imaging.

NMR and IMP are complementary in providing diagnostic and pathogenic information in organic brain disorders.

Family stress and strain in carers

Dr Mary L. M. Gilhooly, University of Glasgow

Most dementing old people are cared for in the community by relatives. Little is known about caregivers' perceptions of dementia or how these perceptions affect coping. Nor is much known about the effects of many years of caregiving on marital and social relations, factors that influence psychological well-being, or whether or not service provision influences caregivers' willingness to continue giving care in the face of continuing deterioration. This paper considers these issues in light of findings from a small scale, intensive interview study of 24 co-resident and 24 non-resident caregivers. The implications of these findings will be discussed in relation to the current government's emphasis on community care.

Decentralised budgets and community care: the cost-effectiveness of this approach with particular reference to the management of the confused elderly

Dr David Challis, Assistant Director, Personal Social Services Research Unit, University of Kent

The community care approach, originally developed in Kent and subsequently replicated elsewhere, was devised to enable social services departments to provide effective alternatives to residential homes and long stay hospital care for frail elderly people. It involved the decentralisation of resources to individual social workers, who act as case-managers, with defined caseload and expenditure limits to ensure accountability, so that more flexible responses to need could be devised and the fragmented services integrated into a more coherent package of care.

The results of the evaluation indicated that when patients were followed over a one-year period more of those receiving the new approach had remained in their own homes and fewer were in long-term care settings. On a range of indicators of quality of life for both the elderly person and their carers there were significantly greater improvements than for those receiving the standard range of services. The costs to the social service department were slightly lower than, and those of the NHS similar to, those of standard provision.

Although the study was not specifically focused on the confused elderly, they comprised about one quarter of the cases. It appeared that the approach involving careful assessment, individual care plans and more flexible responses through control of a budget made it possible to manage the care of these people in their own homes more effectively than has usually been the case. However, the numbers were relatively small and a large study is required to test these observations.

Overall, the findings indicated that effective case-management is an essential feature of more effective home care of the frail elderly. The new approach appeared most appropriate and cost-effective for the extremely mentally and physically frail who were living with others, and also for the less frail, socially isolated elderly person prone to depression.

Forensic psychiatry

A survey of the regional secure units (opened and planned) in England and Wales

Dr P. R. Snowden, Prestwich Hospital, Manchester

In 1975 the Butler Committee on Mentally Abnormal Offenders recommended that each Regional Health Authority provide Regional Secure Units, and central government capital funding and partial revenue funding was made available. Some Regional Health Authorities opened Interim Secure Units by converting existing wards, while plans for Regional Secure Units were being developed. The first Regional Secure Unit did not open until 1980, and the next two units did not open until 1983. In order to investigate the reasons for the delays in opening these permanent secure facilities in England and Wales the plans for each Region were surveyed in detail between October 1982 and March 1984. The progress of each Regional Secure Unit development has been regularly updated, most recently in March 1986. Because of problems with staff recruitment—in particular suitable nursing staff—most of the Regional Secure Units that are currently admitting patients have only opened a proportion of their beds. The link between forensic psychiatrists and the Regional Secure Unit planning process is discussed, as is the relationship between Regional Secure Unit size and site and the type of forensic psychiatry service that can be provided in health regions with different needs, sizes and population densities.

Evaluating secure units—some methodological difficulties

Mr M. J. Berry, Department of Psychiatry, University of Birmingham

This paper illustrates some of the methodological difficulties in evaluating the secure unit programme, based on the work of the RSU Research Unit of Birmingham University. The study was established by the late Professor Gwynne

Jones in 1982 to carry out a three-year evaluation of interim and regional secure units in seven NHS regions in England. Data will be reported on 400 admissions across 11 units. Four hundred variables have been included in the study, but for the benefit of this paper only those associated with the admission pattern will be presented, to highlight both the similarities and differences between the units.

Data will be presented to show some of the characteristics of admitted patients (e.g. referral source, diagnostic label, ethnicity, sex, age, criminal and psychiatric history) and how they vary between regions, and various methods of evaluation of RSUs will be discussed.

The first two years of a Regional Secure Unit and service for adolescents—types of referral made

Dr Susan M. Bailey, Regional Forensic Psychiatric Service, Manchester

A total of 375 patients (264 male, 111 female; age range 11–18) were seen. An open referral system was operated; the majority of adolescents being referred by local Social Services Observation and Assessment Centres. Child, adolescent and forensic psychiatrists referred those adolescents who displayed the most disturbed behaviour.

Types of behaviour most likely to lead to court appearances in both sexes were stealing, damage to property, fire setting, non-school attendance, and (in boys) sexual deviance. Aggression to others (even of a serious nature) was unlikely, particularly in girls, to lead to a court appearance. Over two-thirds of those adolescents who were 'stealing' had no psychiatric illness, the remaining third having predominantly conduct disorders. Fire setters tended to display mixed emotional conduct disorders, as did the boys committing sexual offences. This latter group also contained a significant number of boys with mild mental handicap associated with minor physical handicaps.

Psychotic adolescents presented with a full range of disturbed behaviour, but sadly were not being recognised as psychotic when within the community and were therefore being referred via the penal system or the courts after committing serious offences.

Substance abuse was not a predominant reason for referral, but when assessed, up to 20% of younger adolescents gave a significant history of solvent abuse, and up to 40% of 16–18 year-old boys gave a significant history of alcohol abuse (the latter contributing to their pattern of offending). Surprisingly, few referrals were made because of problems of self-mutilation or abuse. The majority of such referrals were girls, with often a history of sudden maternal death in the preceding two years and subsequent unresolved grief reactions.

The 15 in-patients admitted over a twelve-month period (11 male, 4 female, average age 15½) spanned all diagnostic groups, behaviour leading to admission included violence to self and others, sexual offences, and arson. All our in-patients had histories of a disturbed and chaotic family background and, with the exception of our psychotic youngsters, had all had multiple last placements within the 'care' system. Minor physical handicaps were common as, on examination, were 'soft' neurological signs and abnormal electroencephalograms.

Although only a new service, we are beginning to see within our out-patients and in-patients the not unexpected finding that the greater the number of psychological and social 'insults' an individual receives from an early age the

more likely they are to present with disturbed behaviour in childhood and in adolescence, but perhaps more interestingly we are picking up evidence of previously unrecognised organic features in this patient group. These features may well be contributing to their behaviour, and must be an important factor in the likely prognosis for this group. It is interesting to note that seriously aggressive and dangerous behaviour, with the exception of sexual deviance in boys, was more common in the group of patients who did not have a 'forensic' label.

Changing patterns of admission to and discharges from special hospitals

Dr J. Higgins, Rainhill Hospital, Liverpool

This paper describes a study of patients from the Mersey Regional Health Authority catchment area who were resident in all four special hospitals on 1 January 1981 and those patients who were admitted from or discharged to the Mersey Region between then and 31 December 1985. Comparison is made between these patients and the expected characteristics patient derived from DHSS annual reports into patients in Special Hospitals, the Mersey Region being virtually 1/20th of the population for England and Wales.

On 1 January 1981 the expected total of patients in Special Hospitals was 98 (78 men and 20 women); the Mersey figures were only 84 patients (69 men and 15 women). The possible reasons for these initial discrepancies were reviewed; in view of the techniques employed they are unlikely to be due to sampling error.

Special Hospital patient numbers have declined over the study period, and the Merseyside total has declined in parallel. By 31 November 1985 the expected total was 84; the actual total was 68. The number of female patients has remained virtually static, but the number of male patients has dropped considerably. The changes in the Mersey male patient population are due primarily to the marked decline in those suffering from psychopathic disorder. The number classified as mentally ill (all chronic schizophrenic patients) and mentally handicapped remained virtually constant.

Over the study period 43 males and 10 females were discharged. Of these, 19 males and four females were admitted to the Regional Secure Unit, nine males and four females to mental illness and mental handicap hospitals, and eleven males and two females were discharged to the community. Two males were returned to prison and two males were dealt with otherwise. This pattern highlights the fact that the Regional Secure Unit is playing its role but not to the exclusion of the other appropriate agencies.

Over the study period 26 males and 11 females were admitted to Special Hospitals. Of the males, 15 are suffering from mental illness (two of whom were recalled); six males were suffering from psychopathic disorder, of whom three were recalled. The females were quite equally divided by diagnosis, and only one was recalled. A feature of both sexes is that the percentage admitted from the Regional Secure Unit has steadily increased between 1981 and 1986, in males at the expense of admissions directly from court and in females at the expense of admissions from other psychiatric hospitals. Although the figures are small, there is a clear trend towards the Regional Secure Unit being used as the placement of choice as a place of trial for discharged Special Hospital patients, the patients then being admitted

or returned to the Special Hospital if they proved to be chronic and dangerous.

Only those patients who were formally discharged from Special Hospitals were considered for the study; those sent to the RSU on trial leave were not included. As the patients remaining in Special Hospitals over the study period have become more chronic and more handicapped, there has been a change toward trial leave being the preferred mode of admission of Special Hospital patients to the RSU. This became more prominent in 1984 and 1985, thus making the number of patients remaining in Special Hospitals artificially low.

Child and adolescent psychiatry

Some psychiatric aspects of childhood epilepsy

Professor D. C. Taylor, University of Manchester

Epilepsy is a recurrent, transient brain dysfunction with altered consciousness associated with abnormal electrical discharges. It is best regarded as one form of brain dysfunction which may betoken the co-existence of other forms of brain abnormality, damage, or dysfunction. Epilepsy will often be associated with cognitive and behavioural disorder. Good prevalence estimates suggest that 1250 people will be in current care for epilepsy in the average district of 250 000 people. Half these people will have started epilepsy in childhood. Epilepsy is socially aversive. It is experienced by the public in a variety of guises; a transient severe fright, a wrecker of lives; or a killer. There are destructive, benign, and persistent forms, and the onset of epilepsy opens a variety of possible futures from the grave to the relatively trivial. These forms are discussed in detail.

Temporal lobe epilepsy is among the persistent forms, and is frequently related to lesions in the brain which provide a potential model for understanding hemispheric function in emotional, cognitive and behavioural spheres. Some of the evidence will be reviewed. Threats, losses and burdens abound in the care of children with epilepsy, and these are the stock-in-trade of psychiatric practice. Psychiatrists can improve adjustment. The nosology of the syndromes of cerebral dysfunction in childhood deserves attention.

Vulnerability factors, provoking agents and emotional disorders of school-age children

Dr I. M. Goodyer, Royal Manchester Children's Hospital

The association between environmental adversities and psychiatric disorder in childhood and adolescence has been the subject of considerable research over the past 20 years. Family, school and social factors have received varying degrees of attention according to the questions being asked and the interests of the professionals concerned. That adverse environments are significantly associated with emotional and behavioural disorders is firmly established.¹ However, the mechanisms by which these adversities exert their effects is less clear, and recent research has been examining this question in more detail.^{2,3} Recent research has established that recent stressful life events are associated with emotional and behavioural disorders as well as relatively long-standing adversities.⁴

The Manchester project on emotional disorders has looked at the relative contribution recent stressful life events make in the presence of other adversities, and one

aspect of our research has been to examine the role of adverse maternal factors in the presence of recent stress. A consecutive sample ($n=100$) of school-age children aged 7–16 years presenting with predominant features of anxiety or depression were compared with community controls free of psychiatric disorder and of the same age, sex and social class ($n=100$). We investigated four maternal factors (past and present psychiatric disorder, maternal supporting relationships, and the presence of potential attachment difficulties during pregnancy and in the first six months of the patient's life) and their association with emotional disorder in the presence and absence of recent stressful life events. All four of the maternal factors are significantly associated with emotional disorders before recent life events are taken into account. When the maternal factors are examined in the presence or absence of recent life events we found that (a) past and present psychiatric disorder in the mothers is associated with emotional disorder in both the presence and absence of events; (b) poor maternal support is associated with emotional disorder in the absence, but not the presence, of events; (c) potential attachment difficulties are associated with emotional disorder in the presence of life events but not in their absence (although nearly twice as many cases as controls report such difficulties without events). These preliminary results suggest that with the possible exception of early attachment difficulties the maternal factors examined in this study are more likely to exert a direct effect on disorder rather than be mediated through stressful life events, thus possibly operating as ongoing difficulties (i.e. provoking agents). The results do suggest that different maternal factors may exert different effects on disorder, and that further exploration of the relationships between maternal factors and recent stresses may reveal interactions of importance.

Psychological aspects of children's consultations in primary care

Dr E. Garralda, Booth Hall Children's Hospital, Manchester

Work with children takes up a considerable amount of doctors' time in primary care, and it is generally assumed that general practitioners will undertake the total medical care of children in their practice, including both physical and psychological health. However, little is known about psychological disturbance in children presenting to general practitioners.

We carried out a study of psychological aspects of general practice consultations of children aged 7–12 years. Emotional or behavioural symptoms were the main presenting complaint in only 2%, but we found, from parental questionnaires and interviews, psychological disturbance to be present in a quarter. There was a trend for rates of

psychological deviance to be higher among attenders than in the general population, although this difference was marked only in the more socially advantaged areas. In the general practice sample psychiatric disorder was slightly more common in girls than in boys, and emotional disorders were diagnosed more often than pure conduct disorders. Some somatic symptoms were especially likely to feature as presenting complaints in disturbed children. Psychiatric disorder was associated with psychosocial disadvantage (e.g. broken homes or a family history of psychiatric disorder), and with high current levels of stress by the parents in relation to their children.

It is important to explore further the mechanisms which may underlie these consultations and the part primary care services could play in the recognition of childhood psychiatric disturbance and in interventions to alleviate the effects of this on the children and their families.

Anorexia nervosa in historical perspective

Dr William Ll Parry-Jones, Highfield Adolescent Unit, Warneford Hospital, Oxford

Despite the topical importance and obscure aetiology of anorexia nervosa, systematic historical research has been very limited and the potential sources have never been evaluated critically. This study is based on an extensive search of a wide range of printed and manuscript material concerned with self-inflicted fasting and its effects, principally from Western Europe, from the 16th century onwards.

This information falls into three categories: (a) accounts of spiritual fasting and asceticism, which range from mediaeval saints to 19th century recipients of stigmata, whose resemblance to modern anorectics is notable; (b) descriptions of famous abstainers, freaks, and exhibitionists, including proven imposters and a small number of male 'living skeletons'. Such instances maintained a high level of public interest in fasting, and incredulity about its veracity, (c) a wide variety of medical cases and clinical material. Numerous descriptions of food refusal and abstinence, abnormal appetites and bulimia, mainly in women and associated with amenorrhoea, have been traced from the 16th century to the present. Virgin's disease (chlorosis), and the 'classic' descriptions of anorexia nervosa by Gull and Lasèque in the 1870s are set in historical perspective. A survey of 19th century hospital archives allows an analysis to be made of clinical disorders resembling anorexia nervosa. Brief reference is made to the re-emergence of anorexia nervosa as a psychogenic disorder in the 1940s, after diagnostic confusion with pituitary insufficiency.

Abnormal eating and very low body weights have attracted public curiosity and engrossed the interest of medical men for generations. The cumulative evidence suggests that modern anorexia nervosa is the current variant of a psychopathological entity which has spanned centuries. The central feature remains self-inflicted starvation in young women, but the syndrome has taken different forms, and its interpretation has altered, influenced by contemporary socio-cultural factors and developing medical knowledge. Such morphological changes have implications for present-day clinical practice. Fashionable aetiological ideas and therapeutic approaches need to be re-appraised in the light of these findings, whose relevance therefore exceeds mere antiquarian interest.

Psychopharmacology

Autonomic pharmacology in anxiety

Drs E. Szabadi and C. M. Bradshaw, Department of Psychiatry, University of Manchester

Although it is well recognised that anxiety is accompanied by increased sympathetic activity,¹ it is not known how this would affect the pharmacological responsiveness of sympathetically innervated tissues. We have studied the responsiveness of eccrine sweat glands, a tissue innervated by cholinergic fibres, to intradermally injected carbachol. A plastic paint impression method was used to count the number of active sweat glands.² In Experiment 1, the pharmacological properties of sweat glands were established: carbachol evokes a dose-dependent activation which can be antagonized by atropine.³ In Experiment 2, responses to carbachol were compared in a group of anxious patients and a group of sex and age-matched controls: in the anxious patients, more sweat glands, could be activated than in the controls.^{4,5} In Experiment 3, the effects of 'stressors' (heat, mental arithmetic) were examined in healthy volunteers; the stressors resulted in the same change as anxiety.⁶ In Experiment 4, the effect of diazepam (10 mg) on heat-evoked sweat gland hyper-responsiveness was examined; it prevented the development of hyper-responsiveness.⁷

These results are consistent with the hypothesis that the sensitivity of sweat glands to muscarinic receptor stimulants, such as carbachol, is modulated by sympathetic activity. The increased sympathetic discharge characteristic of anxiety states would sensitise the sweat glands to the agonist, and this response can be prevented by benzodiazepines, drugs known to reduce sympathetic output.

Role of serotonin in punishment, depression and anxiety

Dr J. F. W. Deakin, Department of Psychiatry, University of Manchester

For many years abnormalities in brain 5-hydroxytryptophan (5HT) neurotransmission have been implicated in the

aetiology of anxiety and depression and in the mechanism of action of anxiolytic and antidepressant drugs. However, the precise role of 5HT remains controversial. Animal experiments suggest that 5HT neurones mediate effects of punishment on behaviour. These theories have generally failed to account for the various behavioural effects of punishment or to incorporate roles for different 5HT sub-systems. In response to these deficiencies it was proposed that: (a) spinal 5HT projections mediate unconditioned escape, withdrawal and analgesic responses to noxious stimuli; (b) 5HT projections from the dorsal raphe nucleus (DRN) to basal ganglia and amygdala function as a negative incentive system to guide the organism away from conditioned aversive stimuli; and (c) 5HT projections from the median raphe nucleus (MRN) to hippocampus mediate cessation of behaviour when expected rewards fail to materialise. More recently evidence has emerged for the existence of 5HT receptor subtypes. 5HT₂ receptors may be associated with DRN, and 5HT_{1A} with MRN functions. This theory predicts that anxiety and depression result from excessive operation of 5HT punishment systems.

To test this theory, a neuroendocrine index of 5HT neurotransmission has been evaluated in normal subjects and in depressed patients. In normal subjects infusion of the 5HT precursor tryptophan induced increased in growth hormone (GH) secretion which appear to be mediated by 5HT₁ receptors. In depressed subjects GH responses to tryptophan were markedly attenuated. These results suggest an association between reduced 5HT₁ neurotransmission and depression. Implication for 5HT-punishment theories are discussed.

Monoamine mechanisms in animal models of anxiety and depression

Professor J. A. Gray, Institute of Psychiatry, London

There is good evidence from studies of analogues of anxiety in a variety of animal species that this emotion is in part mediated by increased activity in central noradrenergic and serotonergic pathways, with a more limited activation of certain dopaminergic pathways. A particularly important role appears to be played by ascending and descending projections from the noradrenergic nucleus, the locus coeruleus, in the brain stem. Studies of the neurochemical mechanisms that mediate behaviour in animal models of depression are much more equivocal. They leave open two diametrically opposed views of the neurochemical basis of depression: (a) that this state reflects decreased monoaminergic (and especially noradrenergic) function; and (b) that it reflects increased monoaminergic function. It is possible that both views are correct, but in relation either to events in different regions of the brain or to different kinds of depression. According to the view that depression reflects decreased monoaminergic functioning, this state is at least to some extent the polar opposite of anxiety, according to the converse view, it is closely similar to anxiety. There are insufficient data to resolve these issues fully, but possible solutions are discussed.

The value of pharmacokinetic studies of neuroleptics in clinical practice

Dr Sorn D. Soni, Prestwich Hospital, Manchester

Depot neuroleptics have been in clinical use for almost 20

years, during which time their clinical efficacy has been convincingly demonstrated. Pharmacokinetics of neuroleptics have been extensively studied, but the depot drugs, until recently, had not received as much attention. This paper reports on some recent studies conducted in Salford on the kinetics of depot neuroleptics. The three main areas discussed are (a) the blood level profiles of depot neuroleptics; (b) skeletal muscle factors affecting blood levels of these drugs; and (c) interaction with other psychotropic agents commonly used in psychiatry.

The findings suggest that blood level profiles of depot neuroleptics are not identical, and this may have clinical implications. Typical profiles of fluphenazine decanoate showed an initial peaking of blood levels within 12 hours of injection—a phenomenon not observed with flupenthixol. This observation may correlate with the reported occurrence of side-effects with this drug during this period. Withdrawal studies showed that these agents have a very slow elimination rate, which may be important in the timing of occurrence of relapses after withdrawal and the duration of side-effects when these develop.

The depot neuroleptics are injected into skeletal muscles, and local factors may alter the kinetics of these drugs. Three such factors were studied in a series of experiments. The data suggested that, contrary to the findings with aqueous injections, skeletal muscle activity and massage of the site of injection did not significantly affect blood levels. Nor did changing the site of injection have any effect on the blood level profiles of fluphenazine decanoate.

Finally, the study of concomitant administration of procyclidine and fluphenazine produced data suggesting a significant interaction between these two drugs. The significance of this cannot be underestimated in view of the fact that they are frequently prescribed together for the treatment of schizophrenia.

The overall relevance of pharmacokinetics studies to clinical use of depot neuroleptics is discussed.

Alcoholism: A doctor is required

Professor Neil Kessel, Department of Psychiatry, University of Manchester

Arguments are rehearsed why medical men must take a part in the assessment and treatment of alcoholics and not abdicate their necessary medical role to other professionals or to Alcoholics Anonymous.

Dimensions of neurosis

Professor David Goldberg, Department of Psychiatry, University of Manchester

A brief introduction is given to latent trait analysis, as a way of examining relationships, both between symptoms and between various kinds of research diagnosis. It is argued that two dimensions are sufficient to account for the relationships between common symptoms that occur in patients seeking help from primary care physicians. These dimensions are anxiety and depression, and they are shown to be highly correlated with one another. The diagnosis of 'depression' by general practitioners is shown to have too high a threshold on the depressive dimension, and to be unsatisfactory in another important respect as well.

Liaison with other disciplines

Psychological aspects of paediatrics

Professor David C. Taylor, University of Manchester and Professor R. D. H. Boyd, Royal Manchester Children's Hospital

The Professors of Child and Adolescent Psychiatry and of Child Health ran weekly clinical seminars for two separate groups of students. The students were in their fourth year, during a nine week resident paediatric term. The usual structure was of one or two clinical case presentations by students. Common problems in paediatrics were chosen, and the discussion amplified by cross-questioning of all the students to elicit and promote attention to the relevance to psychosocial factors. The sessions provided recurrent opportunities to orientate students towards the emotional, developmental and psychological aspects of their cases. In addition, the relevance of child psychiatry to child health was manifestly acknowledged, and for us the rounds provided an insight into the development of clinical scales and attitudes in students. These themes will be discussed, as will student understanding of: history taking; normal child development; attachment, threat and loss; and parenting and family structure.

Routine psychological screening of medical admissions by medical students

Professor J. M. Evanson, University of Manchester and Dr G. McGrath, University of Manchester

The large majority of patients with psychiatric illnesses present to, and are treated by, physicians. This study investigated whether such illnesses can be detected by a simple screening procedure administered by non-psychiatrists—in this case medical students. All patients admitted to the Professional Medical Unit of the University Hospital of South Manchester were screened for psychiatric symptoms using the 28-item version of the General Health Questionnaire, administered by medical students attached to the Department of Psychiatry. Patients with high scores were then interviewed by a medical student, using a semi-structured brief interview designed to elicit symptoms of minor psychiatric illness and relevant related social factors. The patient's responses also allowed psychiatric diagnoses to be made using operationalised criteria. Patients who had been interviewed were then seen by a staff psychiatrist on a regular teaching round held on the medical wards.

There was minimal disruption to the routine of the medical ward, and the regular contact with psychiatrists was welcomed by staff. Over one-third of patients were found to have a diagnosable psychiatric illness. The medical students' assessments were in broad agreement with those of the staff psychiatrist, although agreement was much better for the presence or absence of illness than for the strict diagnostic category. An additional benefit was the detection of a considerable amount of previously unrecognised, potentially treatable psychiatric illness in medical patients. The interview schedule could be improved by the addition of screening questions for alcoholism. Overall the study showed that the presence of psychiatric morbidity can reliably be identified using a simple screening procedure requiring little or no training. Whether detection of such morbidity leads to improvement in health care is yet to be determined.

Alcohol

A community alcohol team: A model for the future

Dr E. Owens, Kingswood Clinic, Manchester

During the past 20 years there have been major changes in treatment philosophies with increased recognition of the psychosocial aspects of problem drinking. Initially, treatment was thought to be best carried out in specialist units. Now it is recognised that, in the course of their work, primary care agents frequently come into contact with problem drinkers. Thus community agents could have an important role, not only with early identification and referral but also in carrying out treatment. Surveys, however, indicate that these agents have been slow to develop this role and that they are not even recognising the contribution of alcohol to the problems of their patients. Reasons for this are examined.

To try to overcome these problems, Community Alcohol Teams (CATs) have been set up in many parts of the UK. They are multidisciplinary, varying in size, composition, methods, and aims, but most seek to enable the primary care workers themselves to identify and manage patients. Different models and some aspects of their functioning are described.

Research findings are reviewed. Changes in knowledge and attitudes of the primary care worker have been demonstrated. Changes in professional practice of these agents have not yet been systematically evaluated, nor has the impact of the CAT on patients in terms of outcome. With regard to the secondary services, the CAT should be seen as part of a comprehensive response, not as an alternative.

Preventing alcohol problems at the local level

Professor D. Robinson, The University of Hull

Over the past 20 years, as alcohol consumption in Britain has doubled and every indicator of alcohol-related harm has shown a substantial increase, there has also been an increase in professional and public awareness of alcohol problems and of the need to prevent them. In recent years too, the prevention of alcohol problems 'at the local level' has begun to be taken seriously. In this short presentation I briefly review some features of the prevention debate, emphasise the potential for a local prevention strategy, outline the structure of a new guide to local action, indicate the range of topics covered by it, and in conclusion stress the complementarity of local and national prevention activity.

Liberalisation of licensing law: A Scottish success?

Mr S. Allsop, Research Fellow/Lecturer, Alcohol Studies Centre, Paisley College of Technology, Scotland

The liberalisation of Scottish Licensing Law over 1976 and 1977 involved a number of changes. These included an 'extra hour', whereby licensed premises closed at 11 p.m. rather than 10 p.m., and the opening of public houses on Sunday. These two changes moved the previously restrictive Scottish legislation into practice similar to that of England and Wales. What little evidence there is suggests that these changes were perceived to be popular, successful and were associated with the same amount of alcohol being consumed over a longer time period. A further change allowed premises to open throughout the afternoon. This has proved more controversial.

DRUGS

It has recently been suggested that there has been little increase in alcohol consumption since 1976, and that there have been similarly small increases in indices of harm. This has been the basis of claims that the new laws are an unqualified success. Unfortunately, these claims take no account of the effects of the recession, nor of the increase in the real price of alcohol since 1980-81. It is apparent that these latter factors have had an impact on alcohol consumption, and indices of harm, not only in Scotland but also in England and Wales where no changes in licensing law occurred. Many indices of harm in Scotland have, in fact, remained as high as in 1976 or are higher. Any decreases that have occurred are explicable in terms of the practice of the health and judicial services. It is clear that alcohol-related harm in Scotland is still greater than in England and Wales. This evidence is not consistent with claims that Scottish drinking behaviour is now more civilised as a result of changes in the licensing law: no benefits of the liberalisation have been demonstrated.

Given the recession and other economic effects on levels of consumption in Scotland, along with evidence that those countries with the most liberal licensing laws and easily available alcohol have the highest consumption and alcohol problems, the stage appears set for a rapid increase in problems. The claims of success of the 'Scottish experiment' and the case for liberalisation of licensing laws in England and Wales are without foundation.

Drugs

The drug scene: then and now (1960s London versus 1980s province)

Dr J. H. P. Willis, Liverpool Drug Dependency Clinic

This anecdotal paper compares and contrasts some of the clinical, psychosocial, demographic and pharmacologic aspects of diamorphine-dependent patients seen in the 1960s as opposed to the 1980s. A Drug Dependence Clinic at St Giles' opened in 1967; the author was Consultant Psychiatrist to that clinic until 1976. The demographic, clinical and psychosocial data of that clinic population had been described in the *British Journal of Addiction* (1978), 227 self-injectors of diamorphine were followed up from 1967 to November 1975. The patient population was noted to have a tendency towards a relatively long history of drug usage, e.g. 22% had been self-injectors for 2-5 years, 26% from 6-10 years and 10% for 10 or more years. The incidence for such amphetamine disorders as amphetamine-induced psychoses, hepatitis, pneumonia and septicaemia was high. 33% of the patients had had hospital admission for amphetamine-induced psychoses, 59% had had clinical hepatitis, 11% pneumonia, and 26% septicaemia.

The psychiatric background of the patients contained a high incidence of personality disorder; this was clearly diagnosable in 46%, and an additional 20% were clearly sociopathic, with persistent truancy, delinquency, etc., and there was a 13% death rate (the majority from barbiturate overdose). In other words, these were a group of extremely disturbed individuals in very poor physical shape.

After an absence of nine years from the UK the author returned to England to work in the Drug Dependency Clinic in Liverpool. Here the picture had changed dramatically. 95% of the diamorphine-dependent patients smoke heroin rather than inject it, although there is a hard core of

'old-fashioned' self-injectors—relics from the 1960s, the majority of whom are disturbed, unstable individuals who have never been able to contain control or manage their drug usage. The typical 'new' diamorphine user is aged between 19 and 21, smokes diamorphine by inhalation and shows a moderate pattern of dependency of no great severity—as evidenced by the fact that on admission to hospital such individuals display minimal withdrawal symptoms, require little or nothing in the way of medication, and achieve a normal sleep rhythm within one week.

At an impressionistic level they come across as perfectly normal youngsters who have acquired the heroin smoking habit and consequent dependence from peer group pressure or boredom. They do not have major psychological problems, and it is questionable whether they need psychiatric treatment. Their general state of physical health is greatly superior to that of their predecessors, their nutritional state is good, and they are well dressed and tidy in appearance and as far removed from the old-fashioned stereotype of the 'street junkie' as is possible to believe. Their presence in the community raises serious unanswered questions as to future management.

Out-patient treatment for heroin misusers; outcome with and without parental involvement

Dr P. K. Menon, Arrowe Park Hospital, Merseyside

Fifty patients who had reported physical dependence on heroin and had been treated as out-patients at a regional drug dependence service were traced between 6 and 12 months after entering treatment. All had received out-patient detoxification, by a 14-day methadone withdrawal regime, and counselling. The first 25 subjects had been counselled individually, the remainder with their parents. Forty-three patients were interviewed (23 without and 20 with parental involvement in therapy). Nine subjects interviewed outside prison reported abstinence, which was confirmed by urine testing. Parental involvement made no difference to outcome in respect to abstinence and other changes in heroin usage, or to criminal activity. Heroin smokers were no more likely than injectors to abstain or decrease heroin use. It is likely that abstinence and decreased heroin consumption were spontaneous changes unrelated to treatment.

Psychotherapy

The process of outcome in prescriptive versus exploratory psychotherapy: new findings from the Sheffield Psychotherapy Project

Dr D. A. Shapiro, MRC/ESRC Social and Applied Psychology Unit, University of Sheffield

The Sheffield Psychotherapy Project is a process-outcome study in which 40 professional and managerial workers with depression or anxiety received eight sessions of each of two treatments in a crossover design, with each patient seeing the same therapist throughout. As previously reported, outcomes were somewhat superior for prescriptive (cognitive/behavioural) than for exploratory (Hobson's conversational model) therapy, in a context of substantial overall clinical improvement; outcome was unaffected by the order in which the two treatments were undertaken. This paper presents our efforts to link process to outcome, and thus to identify the effective ingredients of the two treatments. Data

are presented which. (a) compare the trends in target problems rated three times weekly by patients throughout both types of treatment; (b) examine individual differences among patients and therapists as moderators of the outcomes of the two treatments; (c) detail verbal process differences in both client and therapist behaviours in the two treatments and relate these to session impacts; and (d) compare the helpful and hindering impacts reported by patients in the two treatments using a new and efficient method of interpersonal process recall

Substance abuse in the community

Professor Lee N Robins, Washington University School of Medicine, USA

After a long history of epidemiologic investigations of alcohol and illicit drugs limited to assessing patterns of use, the frequency and patterns of dependence and abuse are now being assessed. One such study is the Epidemiologic Catchment Area project, carried out in five sites in the USA. This set of surveys covers both household and institutional populations. It asks about history of problems resulting from substance ingestion over the lifetime, making it possible to study precursors of first involvement with substances and predictors that early problems will continue.

Many of the findings confirm results of much smaller and less representative follow-up studies: conduct problems in childhood and parental substance abuse are powerful predictors; substance use beginning early in adolescence has a much more serious prognosis than does later onsets. But unlike follow-up studies, community-wide surveys allow comparison of experiences of different age cohorts. Disturbing evidence for rising rates is found, particularly among women, for disorders that are already extremely common.

Because the samples are so large, it is possible for the first time to describe groups too rare to be studied in most general population samples. Thus we have adequate samples of cocaine and heroin users, and describe their demographic characteristics and treatment experiences.

Teaching interview methods

Teaching psychotherapeutic interviewing to trainees in peripheral hospitals

Dr G. P. Maguire, University of Manchester

A teaching package of three videotapes with accompanying written material was developed to provide introductory teaching in a method of psychotherapy. Twelve trainees from non-teaching hospitals were compared with 12 teaching hospital trainees previously studied. The research showed that both groups of trainees showed significant changes in interview behaviour both in style and content after this brief teaching introduction.

A further comparison within the group from non-teaching hospitals between trainees taught by teachers who were experienced or inexperienced in using these structured videotapes showed that there were no significant differences attributable to the trainer's experience.

It is concluded that the teaching package is an economic and effective way of introducing basic psychotherapy skills to all psychiatry trainees before they receive clinical supervision. However, the key role of the psychiatric clinical tutor in developing this training in practice is emphasised.

Traps, dilemmas and snags—Focusing in brief psychotherapy *Dr A. Ryle, St Thomas' Hospital, London*

Behavioural, cognitive and psychoanalytic methods of time-limited psychotherapy have all been shown to be effective. A cognitive model is proposed within which methods from the different sources can be combined. The main specific feature of the approach is in the method of reformulating the patient's problems. Therapist and patient together elaborate during early sessions a list of distinct, accurate descriptions of the repeated mental and behavioural sequences underlying the patient's problems. These target problem procedures are the basis for defining the aim of therapy. Cognitive and behavioural tasks and transference work are related to these formulations, and patients have a specific homework assignment of learning to recognise and modify these procedures as they occur. The balance of different methods tried can vary according to therapist and patient preferences and capacities. The method has been applied successfully to an NHS out-patient population.

Problem-orientated interviewing in general practice

Dr Linda Gask, Withington Hospital, Manchester

The problem-orientated approach to interviewing is briefly described on video tape. It is shown that the interviewing skills of general practice trainees can be significantly changed as a result of training in this model, and that this also results in an increased accuracy in detecting psychological illness. These findings strongly suggest that such teaching can be effectively carried out with GP trainees in a group setting.

Care of new long-stay patients

Evaluation of a hostel ward in Manchester

Dr Keith Bridges, Manchester Royal Infirmary

A controlled cost-benefit evaluation of Douglas House is described, and preliminary results referring to the first two years since it opened presented. Although it has been found unsuitable for some patients, the results suggest that the care of chronic psychotic patients is better in the hostel ward and is cheaper than providing care for similar patients in a psychiatric unit of a district general hospital.

Day care of the new long-stay

Dr Digby Tantam, University of Manchester

Psychiatric day hospitals have an important place in future planning of district mental illness services, and there have been several recent re-assessments of their value. Psychiatric day hospitals have historically served two main purposes: for the treatment of mainly neurotic patients who do not require hospital admission, and for the after-care of mainly psychotic patients who have had in-patient treatment.

The Withington Day Hospital is an 80 place DGH which notionally caters for both types of problem. A census by Dr Graeme McGrath and myself demonstrated, however, that the day hospital was dominated by the after-care function and that many of the new long-stay or the potentially long-stay were day and not in-patients. A rehabilitation service was instituted for these patients, and has been evaluated by Dr McGrath and myself. The results of the evaluation show: very small gains in the patients who remain in the day hospital; that a greater proportion of

patients were discharged than were discharged from a group of matched controls; that short-term in-patient admission was more common in both discharged and non-discharged rehabilitation patients; and that discharge had not resulted in symptomatic or social deterioration at the end of the follow-up period.

It is suggested that the results of this study throw doubt on the value of day hospital attendance for many long-stay day patients. It is argued that day-hospital attendance with the negative goal of preventing deterioration is particularly likely to lead to dependency on the day hospital, and to the augmentation of the new long-stay population in day hospitals. Day treatment may be more successful if it is only to be continued for as long as it produces an improvement in the patient's condition.

A survey of long-term users of psychiatric beds in City and Hackney Health District

Dr Cathie O'Druscoll, Team for the Assessment of Psychiatric Services (TAPS), Friern Hospital, London

City and Hackney Health District has been providing locally-based psychiatric services without mental hospital back-up for over 10 years. The district has acute wards and psychogeriatric assessment wards but no long-stay beds except for ESMI.

Over the past few years, a wide range of accommodation has been set up in the district by the Community Psychiatry Research Unit for chronically disabled patients. Despite these efforts patients were remaining in hospital wards for more than six months, and this survey was commissioned to look at the characteristics of this group. Thirty such patients were identified. The findings are described and the survey recommendations outlined. The survey found that only 20% of the patients were felt to need hospital care on the census date. The others fell into three groups: the elderly psychologically infirm, those with organic brain damage, and resistant or multiply-handicapped functional psychotics. Suitable provision for these patients is currently being planned within the district, and the survey will be updated at regular intervals.

Psychiatry of the puerperium

Maternal depression in the year following childbirth and mother-child interaction

Dr Alan Stein, Warneford Hospital, Oxford

Possible associations between postnatal depression and mother-child interaction were investigated by assessing two groups of mothers and their 19-month old babies. An index group of 49 mothers had experienced emotional disorders (46 depressive and 3 anxious) in the year following childbirth, while a control group of 49 individually matched mothers had been free from psychiatric symptoms in the same period. When the babies were 19 months old, all mothers were re-examined psychiatrically. A week later, mothers and children were assessed at home in three ways: observation of mother and child while carrying out standardised tasks; developmental assessment of the child; and a semi-structured interview with the mother. The assessors of the mother and child were blind to the findings of all the mothers' mental state examinations.

A number of differences between the two groups were found. For example, index mothers scored lower on

measures of positive contribution to their children's activity ('facilitation'), while their children showed less 'affective sharing' (smiling and showing toys to mother, or smiling and vocalising during a joint play). When currently depressed mothers were excluded from the analysis some of these differences persisted, although less strongly.

Within the index group chronic social difficulties appeared to be related to some aspects of mother-child interaction. For example, mothers who had experienced chronic social difficulties showed less warmth and facilitation than those who had not experienced such difficulties, while their children showed less affective sharing.

Maternal mental illness: Behavioural analysis of mother-infant interaction

Dr R. Kumar and Miss Carol Gambles, Institute of Psychiatry, London and Dr E. Melhuish, Thomas Coram Unit, London

Childbearing is associated with a sharp rise in the incidence of psychiatric disorder in women; between one and two out of every thousand recently delivered mothers require admission to psychiatric hospital. Most such women are found to be suffering from post-partum psychotic illnesses, although some mothers with postnatal depressive neurotic disorders are also admitted,¹ possibly because of additional social and interpersonal problems and severe difficulties in coping with the demands of a new baby. In Britain, separation of mother and child is usually avoided by joint admission either into a specialist mother and baby unit or into a general psychiatric ward with improvised facilities.^{2,3} There have been very few systematic studies of mother-infant interactions in such clinical settings in which both the maternal mental illness and the milieu may exert important short, and possible long-term influences on the developing infant and on the relationship between mother and child.

Margison⁴ has described some of the pioneering work which was carried out at the Manchester Mother and Baby Unit in which the clinical management of mothers was considerably facilitated by detailed regular observations by nurses of mothers and babies together. The preliminary research which is described here is an attempt to further systematise clinical observations of mentally ill mothers and their infants. The main aims of this research have been:

- (a) To discern and describe different patterns of interaction and to examine possible correlations with maternal psychopathology.¹
- (b) To make more informed management decisions e.g. concerning regulation of access and the prediction of risk to the child.
- (c) To establish a data base upon which to draw in future studies of the psychological development of children who were admitted as infants together with their mothers, to psychiatric hospitals.
- (d) To try to test whether joint admission to an institution of itself carries disadvantages for the developing child that outweigh possible benefits.

A rating scale has been developed at the Bethlem Royal Hospital which attempts to quantify perceptions by staff of selected aspects of mother-infant interactions. Preliminary results are described and illustrated by a series of case reports.

Long-term consequences of post-natal depression on child development

Dr H. L. Caplan, Consultant Child and Adolescent Psychiatrist, University College Hospital, London

Ninety-four women and their first-born children took part in a longitudinal study of maternal mental health during pregnancy and after delivery. The children's cognitive functioning and behaviour were assessed using respectively the McCarthy Scales and the Behaviour Screening Questionnaire, but without knowledge of the mothers' psychiatric history or current health. Significant intellectual deficits, averaging about 10 points, were found in the four-old children of the women who had suffered with post-natal depression. Girls performed slightly better than boys and children from middle-class and professional families did better than children from working-class homes, as did children whose mothers had achieved at least one 'A' level in their high school education. The presence of maternal depression correlated with lower cognitive ability but only when the depression occurred in the first year of the child's life. Behavioural disturbance in the four year-old children correlated with concurrent maternal depression but not significantly with maternal depression in the first year post-natally. The presence of marital conflict and a history of paternal psychiatric problems were independently linked with both lower cognitive test scores and behavioural disturbance and these were the only factors which contributed by interaction to the deleterious effect of maternal post-natal depression.

The effects of parents: What can non-human primates teach us?

Dr M. J. A. Simpson, MRC Unit on the Development and Interaction of Behaviour, Cambridge

The study of monkeys, apes and other animals can offer us principles to consider and test in clinical scientific work with people. Experimental work with rhesus monkeys has yielded some clear-cut and provocative findings. Thus a rhesus monkey reared by her mother out of sight of others is unlikely to accept her own baby easily, unless she sees other mothers and babies sometime in the first 2½ years. Such non-tactual perception can then be enough to engender an accepting attitude which allows her to learn from her own infant. A video-tape of a rhesus monkey giving birth to her first infant illustrates how mother and infant can co-operate.

Studies of human mother-infant interaction are probably now more sophisticated than most studies of non-human primates. The view that very young human infants can contribute substantially to intricate and well-meshed interactions with their mothers was present in work by Middlemore in the 1930s and Klein in the 1950s, before the rise of ethology and primate studies. However, the evidence is only now becoming compelling. For example, Murray and

Trevarthen arranged for mothers and infants to communicate face to face through a video set-up, and could replace the mother's 'live' contribution with part of one of her earlier sequences. When faced with a no longer responsive sequence the infants showed detached unhappy puzzlement. When the mother put on a blank face, the infants worked to reinstate a mutually responsive interaction. The study suggests that the infants used expressions of feeling to assist the mother in establishing mutual awareness, and it acknowledges the debt of infant studies to the ethological traditions of studying expressive communication. Similarly, Bowlby's views of the instinctive bases of attachment system grew out of his discussions with Hinde (a bird ethologist before a primatologist), as well as his psychoanalytic background.

If animal studies have contributed something to the study of loving co-operative exchanges, they also contribute an evolutionary view of individual selfishness, and of preferential treatment to others in proportion to how closely they are related, and/or likely to reciprocate. Infanticide, especially towards unrelated infants of potential mates, and conflict between parents and infants over how much is to be invested in the infant through weaning, are no longer viewed as surprising or necessarily pathological. If we expect weaning infants to conflict with their parents, we should also expect earlier development to lay suitable foundations for coping with conflict, and special weaning problems for those whose parenting was not good enough.

We are looking at the individual development of rhesus monkeys living in captive groups of two to five mothers and their young, and a single adult male. To what extent does an individual develop special ways of coping with its particular social situation, and how is such development guided? For example, status differences between mothers are clearcut and consistent, and result in different maternal and social environments for their infants. Subordinate infants are more often harassed and chased, and have to be much more circumspect in how they move toward favoured companions or foods. By the eighth month when tested with their mother as the only adult present, subordinate infants are more likely to persist in foraging or exploring out of their mothers' reach in situations with novel features which elicit fear and cautious approach in most infants. Such enterprising behaviour is also seen in subordinate jackdaws and reef fishes, and is adaptive to a life in which the opportunity to get near a potentially attractive object may last only while the setting is novel enough to cause others to hang back. If nothing is ventured by one subordinate, something may be gained by another. The dominant infant, in contrast, needs venture forth only when the subordinate has proved the situation safe, and can then easily gain control of whatever goods remain. While subordinates may become enterprising because they often have opportunities to take risks, there may also be constitutional differences in enterprise, and in the degree to which early mother-infant interaction encourages its development.

Draft Code of Practice

Mental Health Act 1983: Draft Code of Practice

Dr J. R. Hamilton, Broadmoor Hospital, Berks

The paper discusses the background to the Code of Practice, originating as it did in the consent to treatment

POSTER PRESENTATIONS

provisions of the Mental Health (Amendment) Bill. The remit of the Code of Practice was changed whilst the Bill went through Parliament to provide guidance on the treatment of all patients, in hospital and elsewhere, suffering from mental disorder. The purpose of a Code of Practice is to provide guidelines on practice which Acts of Parliament and Regulations cannot do. The legal status of the Code is discussed together with the possible consequences of non-compliance. The question is raised as to whether the Mental Health Act Commission has overstepped its remit by including certain matters in the Draft Code such as non-clinical research. Considerable confusion was added to views on consent to treatment last year when the Commission sent to Health Authorities a document on consent to treatment which again has a questionable status. Much of the Draft Code is legalistic and has an anti-medical bias; examples of this are given. No guidance whatsoever is given on the interpretation of the urgent treatment section of the consent to treatment provisions nor on who should be responsible for carrying out the recommendations of a Mental Health Review Tribunal when these are disputed by the responsible medical officer. No guidance is given on treatment in the community for patients on leave of absence. (Mention is made of the problems in treating those who have been conditionally discharged from hospital and are on guardianship and there is a suggestion for legislation to allow for an extension of the consent to treatment provisions to patients in the community: comment is made on the administrative problems surrounding such an extension and how to resolve the potential problems of non-compliance).

It is concluded that much consideration will have to be given to the Draft Code during this consultation stage and that the final Code should not include contentious matters on which there is no consensus. The document should be reduced drastically in size and should not repeat what is going in Acts or the DHSS's memoranda. The final Code should give reasonable and realistic guidance on ways to promote optimum care and at the same time recognise the importance of clinical judgement. Unless this is done there is a danger of the Code being seen as a mixture of patronising and unrealistic advice which will not attract the confidence or credibility of psychiatrists.

Who wears the chains now?

Dr C. J. Thomas, Leicester General Hospital

The Mental Health Commission have drafted a provisional Code of Practice which they wish to impose on the psychiatric and other related professions. The feelings of the vast majority of psychiatrists in current clinical practice is that the draft Code of Practice is totally unacceptable. Most of us had envisaged a code of practice clarifying certain legal aspects of the Mental Health Act (1983) that would make the use of the Act more easily understood. However, the Commission seem to have given themselves a much wider remit and it appears as if they see themselves as determining how psychiatry should be practised in all areas. In their biannual report they admit they wish their powers to be extended to informal as well as formal patients. One must assume that the Commission have the intention in the draft Code of Practice of obtaining ultimately a better service for the mentally ill; unfortunately, it seems as though they believe this should be done by putting excessive controls on the practice of psychiatry. This naive approach is likely to greatly hamper the therapeutic and caring aspects of

psychiatry and will therefore in all probability lead to a considerable deterioration in the quality of care provided for the mentally ill.

The whole concept of a Code of Practice being imposed upon a profession by an outside body with only limited knowledge and experience of the problems and requirements of professional practice is unacceptable. If a Code of Practice has to be drawn up then it should be in a drastically different form than the current draft Code and should be one that is largely produced by the psychiatric profession itself and is acceptable to the members of that profession.

Poster presentations

A survey of blood alcohol levels in self-poisoning cases

Drs R. Varadaraj and J. D. Mendonca, St Thomas, Ontario, Canada

One hundred and fifty-eight cases of overdose were studied for alcohol use following their admission to an accident and emergency department. Of these patients 41% had consumed alcohol and 29% had blood alcohol levels exceeding 17.4 mmol/L (80 mgm/100 ml). Impaired overdose patients were found to be significantly older than non-impaired patients. There was a tendency for higher blood alcohol levels to be more associated with weekends, than weekdays, this association being stronger for males. More female overdoses were impaired on weekdays. Blood alcohol levels of women arriving during 'risk' time (2200-0659) were significantly higher than those of women arriving at other times. These findings confirm that alcoholism assessment and treatment services need to be integrated with accident and emergency services.

A comparison of plasma beta endorphin and ACTH in depression and chronic pain

Drs R. J. Smith, K. H. Simpson and A. G. Oswald, Department of Psychiatry and Anaesthesia, University of Leeds

Depression and chronic pain are interrelated and patients with intractable pain often become depressed. Patients with depression show diminished sensitivity to experimental pain stimuli. Endogenous opioids may be involved in pain perception, however, their role in affective disorders is not clear. Measurement of CSF and plasma opioid activity has produced conflicting results.

Neuroendocrine tests have been used as diagnostic and prognostic indices of depressive illness. Many depressed patients show increased activity of the hypothalamic-pituitary-adrenal axis in response to dexamethasone, and it has been suggested that this may be regulated by endogenous opioids.

Twenty-two patients with chronic pain and 20 patients with primary depressive illness completed a battery of psychological rating scales, and venous blood was withdrawn for beta endorphin and ACTH measurement using radioimmunoassay. The two groups of patients showed subtle differences. The relationship between beta endorphin and ACTH was the most powerful discriminator.

A critical review of research into neurotic hypochondriasis

Dr G. Adams, Department of Psychiatry, Leicester Royal Infirmary, Leicester

This paper was presented in a slightly different form at the 15th European Conference on Psychosomatic Research in

London in 1984. It examines briefly both the pragmatic research which has been done on hypochondriasis and the theoretical bases which have been used in attempting to comprehend this difficult area. It proposes that more phenomenological research is needed and discusses ideas on how this could be organised.

The efficacy of oxypertine in tardive dyskinesia

Drs J. S. Bamrah, H. L. Freeman and S. D. Soni, Research Department, Prestwich Hospital, Manchester

Tardive Dyskinesia (TD) is characterised by abnormal involuntary movements which often involve the oro-facial musculature and sometimes the trunk also. The exact aetiology of the condition is not known although it is thought to be related to dopamine receptor hypersensitivity resulting from prolonged neuroleptic therapy.

Several pharmacological treatments have been tried in an attempt to alleviate the symptoms of TD with conflicting results. One approach would be to look at agents that do not block post synaptic receptors but act through depletion of dopamine by presynaptic mechanisms such as oxypertine. A six-month double-blind, placebo controlled study was undertaken in Salford to evaluate the efficacy of oxypertine in the control of symptoms in patients with established TD. The results of this long-term study were at variance with our previous findings. The data are presented together with its implications which, we feel, extend to all trials for the treatment of TD.

Hormonal responses to i.v. tryptophan in depression

Drs I. Pennell, and J. F. W. Deakin, Department of Psychiatry, University of Manchester

The role of 5HT in the aetiology of depression and in the mechanism of action of antidepressant drugs remains controversial. The repeated finding of reduced csf 5HIAA concentrations and the possible antidepressant efficacy of 5HT reuptake blockers suggest a deficiency of 5HT neuro-

transmission in depression. In contrast, the immediate or delayed 5HT receptor antagonist properties of many antidepressants suggests excessive 5HT neurotransmission may be associated with depression. To discriminate between these theories we have evaluated a neuroendocrine test of 5HT neurotransmission in normal subjects and depressed patients. In normal subjects tryptophan infusions (100 mg/kg) induced increases in growth hormone (GH) and prolactin (PRL) but not cortisol. These responses were not antagonised by high doses of ritanserin, a 5HT₂ receptor antagonist. This suggests that 5HT₁ receptors normally mediate GH and PRL responses to tryptophan.

Twelve patients meeting DSMIII criteria for major depressive disorder were given tryptophan infusions. Their responses were compared with those in nine healthy controls. In depressed patients GH responses were significantly attenuated. Prolactin responses were generally more variable than GH responses to tryptophan and differences in PRL between controls and depressed patients did not reach significance. The results suggest reduced 5HT₁ neurotransmission is associated with depression.

Modification in family therapy with Chinese families

Dr U. Freeston, Senior Specialist in Child Psychiatry, Canberra, Australia

A family approach is now standard practice with Western child psychiatry, but its techniques and attitudes are derived from work with Western families. In what way would these be altered when working with a culture different in traditions, values, patterns of communication and child rearing practices? Specific effects of these differences on family life and on the attitudes of the family to therapy are examined. An attempt is made to identify specific alterations in techniques for these differences. Areas include: economic, money, work, housing, etc., rural to urban—old attitudes and new needs; patterns of communications in the family; values—security versus freedom.

Annual Meeting, 1986

Boldrewood Conference Centre, The University of Southampton
(8–10 July 1986)

Seasonal affective disorders

Light treatment of normal volunteers: effects on mood performance and melatonin rhythms

Drs J. Arendt, Department of Biochemistry, University of Surrey, J. Broadway, Department of Biochemistry, University of Surrey and British Antarctic Survey, Cambridge and S. Folkard, MRC Perceptual and Cognitive Performance Unit, Laboratory of Experimental Psychology, University of Sussex

The treatment of seasonal affective disease (SAD) with bright light in a short, or long 'skeleton' photoperiod (daylength) derived from the observation that human night-time melatonin production is only suppressed by a light intensity > 2500 lux. We were concerned to establish the effects of skeleton photoperiod bright light in normal subjects as part of a study of human photoperiodism. The Antarctic (Halley base, 75°S, 25°W) provides an interesting environment for such studies both with regard to the natural, extreme changes in daylength and to the long period (three months) of winter darkness where the only available illumination is artificial (< 500 lux).

For six weeks following the winter solstice the artificial photoperiod was manipulated with bright or dim artificial light: two groups of five male subjects were exposed from 0800 to 0900 h and from 1930 to 2030 h to either bright (2500 lux, Vitalite, Durotest Corporation) or dim (< 500 lux) supplementary lighting. Plasma samples were taken from volunteers via indwelling venous cannulae at hourly intervals for 25 h at equinoxes, solstices and at the end of light treatment. The samples were assayed for melatonin by radioimmunoassay.

Subjects recorded mood (on 18 visual analogue scales), oral temperature, and performed logical reasoning, letter cancellation and pegboard transfer tests six times daily (0900, 1100, 1400, 1600, 1830, 2200 h) during the week before light treatment and during the last week of light treatment. No major differences were found in mood, temperature or performance during light treatment. Both season and light treatment influenced melatonin. Bright light in the winter induced a two-hour phase advance in the melatonin rhythm (overall analysis of variance pre-compared to during light treatment, $P < 0.00001$; statistical difference in phase position, $P = 0.0402$; dim light treatment: no effect). A similar phase advance was seen in summer compared to winter (overall analysis of variance, $P = 0.0247$).

We conclude that in this exceptional environment a clear physiological response—phase-shifting of the melatonin rhythm—is seen during bright-light treatment given as a 12.5 h skeleton photoperiod, with no major concomitant effects on mood, temperature or several performance variables. Seasonal changes in human melatonin production are probably dependent on photoperiod.

Seasonal affective disorder (SAD—Does it exist?)

Drs G. Isaacs and C. Thompson, Charing Cross & Westminster Medical School, London

SAD, originally described in 1984 by Rosenthal et al, is a condition of regularly recurring autumn-winter depressions, separated by spring and summer remissions. It occurs predominantly in women who complain of fatigue, hypersomnia, overeating, carbohydrate craving, weight-gain and sadness.

In the first part of the paper, the first British sample ($n = 51$) to be described were compared in terms of their clinical and demographic characteristics with American and Swiss groups. They were shown to be remarkably similar in terms of their atypical symptomatology despite this not having been part of the inclusion criteria. The main differences were a lower incidence of the Bipolar II diagnosis and less frequent family history of affective disorder in the British sample.

In the second half of the paper, an intervention study in 11 patients was described. The aims of this part of the study were to investigate whether the total amount of light or extension of the photoperiod was the important variable. To this end, three different treatment regimens with full spectrum lighting were used in each patient. The treatments were given in a balanced randomised order for one week, followed by a withdrawal week. They were photoperiod extension by four hours with either bright light at 2,500 lux or dim light at 300 lux, and four hours of incident light augmentation with bright light at 2,500 lux given within the photo-period so as not to alter its length.

Observer ratings of depressions by a blind rater, using the 17-item Hamilton Depression Rating Scale and a specially compiled atypical symptom rating scale, showed augmentation to be significantly better than photoperiod extension by bright or dim light. However, self rating, showed photoperiod extension with bright light was significantly better than the other two treatments. Thus the superiority of bright over dim light was replicated while the blind observer ratings suggested that photoperiod extension was not essential to the action of phototherapy.

Mood disorders, infradian rhythms and seasons

Professor M. R. Eastwood, Clarke Institute of Psychiatry, Toronto, Canada

Recently there has been a developing interest in the relationship between affective disorders and season. Epidemiological data from disparate centres suggest that affective disorders (and suicide) are seasonal in that they peak in the spring and fall. This finding excites interest since it implies that this type of illness is predictable in part—clearly significant for prevention. Furthermore, the finding may be linked with the current interest in changes of light, mood and melatonin. Our group has shown that the affective disorders and alcoholism (which may well be a reflection of mood disorder) are the only psychiatric diagnoses to show seasonality. Furthermore, the team has examined long mood cycles—*infradian* rhythms—to see whether they exist in those with and without major affective disorders. A lengthy study showed that, of the *infradian* rhythms, 90 day cycles were the most common and occurred in both cases and controls. The cycles differed only in amplitude. This

suggests that affective disorder, like many medical illnesses, is a pathological variant of a physiological variable.

The purpose of the presentation is to link seasonal mood variation with the patterning of the infradian cycles. A group of patients suffering from major affective disorder and a healthy comparison group rated their mood daily for approximately 14 months. The two groups exhibited very similar mood patterns with infradian rhythms synchronising with calendar seasons.

The effect of daylight saving time on the incidence of psychiatric presentations

Dr P. A. Bick and Ms A. L. Hannah, University of Dundee, Scotland

A specific seasonal affective disorder has recently been described. This disorder, typically a winter depression, may be caused by changes in the period of natural daylight (photoperiod) at different times of the year. These photoperiod changes are thought to cause disturbances in circadian rhythm homeostasis which lead to the expression of the seasonal mood change. This postulate is supported by evidence that seasonal depressions can be readily treated with a three to six hour exposure to artificial light and that resolution of the disordered mood is accompanied by resolution of phase disturbed circadian rhythms. We wondered if a sudden change in apparent length of daylight consequent to a one hour time shift (caused by the Daylight Saving Time change) might lead to a phase disturbance in circadian rhythms and an associated increased incidence of affective disorders for a short time following the change.

There have been no previous reports of Daylight Saving Time causing clinically significant changes in behaviour. The authors investigated the effect of five Daylight Saving Time changes on the incidence of psychiatric presentations before and after the time changes at a busy crisis centre. 1,521 patient contacts were reviewed by a rater who was blind to the dates of the records. There were significantly more patient contacts during the week following the time changes. This increase was due to a specific rise in depression and psychosis related presentations. A hypothesis is presented that Daylight Saving Time causes a short term disturbance of circadian rhythms, leading to the expression or exacerbation of psychiatric symptoms.

Influence of sunshine on the prevalence of mania

Dr P. A. Carney, Regional Hospital, Galway, Ireland

Monthly admission rates for patients with a diagnosis of mania to the Department of Psychiatry in Galway Regional Hospital were examined for the five year period 1980-1984. Monthly variation and admission rates were compared with monthly levels of sunshine. The number of admissions for each month over the five year period correlated significantly with the average total hours of sunshine for each month in the same time. It is suggested that the presentation of mania in this fashion is due to an abnormal response to light in patients with the disorder. The data also demonstrated a large increase in the number of admissions over the study period.

The effect of light on CNS noradrenaline and serotonin receptor function

Dr R. Mason, University of Nottingham

Seasonal affective disorder (SAD) is characterised by recurrent episodes of depression which occur annually

during the winter months, corresponding with the periods of shorter daylength and reduced light intensity. Interestingly, the use of bright artificial light is reported to be an effective treatment for SAD.^{1,2} A common result of antidepressant drug and ECT treatment in animal studies is altered 5-hydroxytryptamine (5-HT) and noradrenaline (NA) B-adrenoceptor sensitivity in the CNS.^{3,4} If light therapy is effective in depression then it might also be expected to induce similar changes in 5-HT and NA neurotransmission.

Pigmented male rats were kept on lighting cycles of either LD(12 hr:12 hr), LD(18 hr:6 hr) or under continuous light (LL) for 6-12 weeks. Five-barrel micropipettes were used for extracellular recording from the hippocampus and cerebellum and for the microiontophoretic application of 5-HT, NA and GABA. The sensitivity of single neurones to 5-HT, NA and GABA was evaluated by both the I.T50 and threshold ejection current methods.^{3,4} Both continuous light (LL) and LD(18:6) light exposure resulted in the development of a 2-3 fold supersensitivity to iontophoretic 5-HT (hippocampus) and 2-3 fold subsensitivity to NA (cerebellum) compared with LD(12:12) conditions. The response of neurones to iontophoretic GABA was similar in both LD and LL rats. Altered sensitivity to iontophoretic NA and 5-HT was not found following short periods (1-3 days) of exposure to light. Rats kept under LD(12:12) and treated daily with imipramine HCl (10 mg/kg, i.p., for 3 weeks) also showed a pronounced subsensitivity to iontophoretic NA and supersensitivity to 5-HT compared with saline treated controls. No effect on GABA sensitivity was found.

The similarity between the effects of light-induced altered neurotransmission in the CNS and those induced by antidepressant drugs on 5-HT and B-adrenoceptor function may provide a basis for the recent reports of the beneficial effects obtained with bright artificial light in the treatment of seasonal affective disorder. The light-induced effects may, in turn, be mediated via retinal projections through the suprachiasmatic nuclei (SCN), central structures for the regulation of the circadian and circannual rhythmicity.^{5,6}

WHO and mental health research

Community response to alcohol problems: results from Scotland, Zambia and Mexico

Dr E. B. Rutson, Royal Edinburgh Hospital

The world is producing and consuming more and more alcohol. Total production of alcohol rose by almost 50% between 1965 and 1980. There is evidence that alcohol consumption has increased rapidly over the same period. Existing evidence shows a close relationship between total

consumption and the extent of harmful consequences. Increasing alcohol consumption is, therefore, a major health concern throughout much of the world. Most existing research on alcohol consumption is based on Western industrialised countries and when communities in Africa, Asia or Latin America have been the focus of a study the emphasis has usually been on an anthropological rather than an epidemiological perspective.

The research described here was a collaborative project involving the countries concerned and promoted by the World Health Organization. It aimed to describe the extent and nature of drinking patterns and alcohol related problems in a number of selected communities, alongside a study of that community's attitudes towards alcohol and their current response to alcohol related problems. The overall objective was to provide an information base within each community that would facilitate the fuller development of a more appropriate response to alcohol related problems. It was also envisaged that the experience within these communities would stimulate similar endeavours within the country concerned and within neighbouring countries.

Urban and rural communities were selected within countries of widely differing characteristics; Mexico, Scotland and Zambia. Epidemiological studies within each community revealed very different patterns of consumption in each of the countries involved, although the urban rural differences within countries were less than anticipated. Scotland proved to be a country of near universal alcohol consumption. Attitudes towards adult drinking were tolerant and two thirds of the men and the vast majority of women who had been drinkers reported no problems arising from their drinking in the past year. In Mexico 55% of the women were abstainers as were 15% of the men. In Zambia 32% of the men were abstainers and 69% of the women. In both these relatively abstinent countries attitudes towards drinking were much less tolerant, particularly amongst Mexican women, and the pattern of drinking was more episodic and intense in both countries. Among drinkers in Mexico and Zambia, many of whom consume much less than the Scots, there was a surprisingly high level of reported problems.

The research gave priority to obtaining data which were of principal value to the development of a community response to alcohol problems in the communities involved. There are, however, implications for cross national studies and one community may benefit from the lessons learned in another. The problems of designing and maintaining a project of this kind in widely differing settings are also discussed.

Incidence of schizophrenia: results of the first phase of an international study

Professor J. E. Cooper, University of Nottingham

The International Pilot Study on Schizophrenia (IPSS), conducted in eight Field Research Centres between 1966 and 1972, raised the possibility that patients with schizophrenia living in developing countries (Africa and India) had a more favourable two year and five year outcome than similar patients living in developed countries, (UK, USA, Denmark, USSR). The IPSS was not an epidemiologically based study, so this finding could not be regarded as definite, even though a similar finding was evident in several other studies. Another WHO collaborative international study was therefore undertaken, with a design that allows

more definite conclusions to be drawn. Most of the field research centres in the IPSS took part again, plus several new centres (11 in all). In each centre, attempts were made to identify and follow up for two years all patients presenting to the psychiatric services (and other helping agencies, defined for each centre), serving a defined catchment population, with a first ever psychiatric illness that might be schizophrenia. Screening was on a symptomatic basis, rather than relying on local diagnostic habits. Extensive social and personal data were collected for each patient, since the IPSS showed that the predictive power of social information was at least equal to that of clinical information about the illness itself.

The incidence rates and some of the clinical characteristics of the patients are presented for those centres for which rates can be calculated. They show a surprising similarity, in contrast to the wide geographical and cultural variations found in the incidence of most physical disorders. The relationship of the study (known as the 'WHO Collaborative Study on determinants of outcome of severe mental disorders') to other WHO studies on schizophrenia and social disability is also discussed.

WHO multicentric studies of treatment of selected mental disorders

Professor Max Hamilton, The University of Leeds

Three of these studies have already been published and the next will appear soon. Because of the difficulties and expense in organising such trials, they have to be very comprehensive and this makes analysis and interpretation anything but simple.

Schizophrenia. The study is well known. It found that, on the whole, with adequate definitions, it is easy to agree on the diagnosis of schizophrenia. The features are similar in different cultures.

Schizophrenia follow-up. The most important finding is that in the Third World, the outcome is very much better.

Anti-depressant dosages. The symptoms of primary depressions are remarkably alike across cultures. The higher dosage of drug is very slightly better than lower, but the difference was not significant statistically.

Sedatives and counselling in the treatment of 'somatized' anxiety. This complex study included analysis of the details of counselling and the assessment of life events. Drugs had little effect on this type of patient, but counselling was clearly beneficial.

Biological aspects of depression

Propranolol and depression—causative or coincidence?

Dr R. Manchanda, University of Western Ontario, Canada

Several reports suggest that propranolol commonly used in non-psychiatric patients may cause symptoms of depression and this may be dose dependent. On the other hand, other investigators have argued this relationship to be insignificant. The author reviews the available evidence from case reports, manufacturers' reports of adverse effects, data from hypertension clinics and the tricyclic anti-depressant use among patients on antihypertensives. The findings of propranolol-induced depression may be coincidental as the results are derived from uncontrolled and blind studies and hence are not very reliable. Some investigators have used high doses of propranolol for the treatment of anxiety, mania and schizophrenia. Change in

the ratings of depressive symptoms in controlled trials of schizophrenic patients using high doses of racemic (dl) and dextro(d) propranolol do not lend support to the claim that propranolol causes depression.

Stimulus seizure issues in electroconvulsive treatment

Professor R. McClelland and Drs M. Headley, S. Cooper, J. Lumsden and G. McAllister, Queen's University of Belfast

While electroconvulsive therapy (ECT) has been established as an effective treatment for depressive illness a number of questions remain regarding the optimal form of administration and patient selection. Underlying such questions is the need for a fuller understanding of the kinetics and mode of action of ECT and the development of reliable methods of patient monitoring. It is now generally accepted that the *grand mal* seizure is a necessary concomitant for the therapeutic effects. Several parameters of the induced seizures show considerable inter-subject and intra-subject variability, particularly duration and distribution. While it is less clear that these contribute significantly to outcome, present evidence suggests that local fits, unilateral fits, and fits which last only a few seconds are not as effective as generalised convulsions lasting more than 20 seconds. With the use of muscle relaxant drugs, behavioural observations are not reliable in detecting and quantifying the seizure events. Multichannel EEG monitoring gives a more certain and precise assessment of the occurrence, distribution, duration and characteristics of the induced fit and many would regard neurophysiological monitoring as mandatory in further scientific studies of ECT. In a recent series of double-blind studies we have been investigating the seizure characteristics and clinical efficacy of ECT. This has included a comparison of the Ectron Mk 4 Sine-wave constant voltage stimulus unit (CV) and the Ectron CCX constant current pulsed stimulus unit (CC). Preliminary findings from these studies suggest that the standard stimulus outputs of these two units do not significantly affect seizure duration. Small but significant delays were observed in the onset of bisynchronous seizure activity using CC ECT. Spectral analysis of the seizure events is presently being undertaken.

Major discrepancies were observed between the visually observed and EEG monitored seizures using both the CC and CV stimulus methods. Visual fits were significantly shorter than EEG seizures. Six of 82 (7%) of visually monitored seizures were reported as 'missed'. The corresponding EEG events confirmed the occurrence of seizures in all cases.

Tyramine conjugation deficit, a trait-marker for endogenous depression

Professor M. Sandler, Institute of Obstetrics and Gynaecology, University of London

A highly significant decrease in ability to metabolise an oral load of tyramine to its sulphate conjugate compared with controls and neurotic depressives was identified in patients with endogenous unipolar depressive illness. The biochemical deficit persists after clinical recovery and is present in about half the non-depressed first degree relatives of endogenously depressed probands. Thus it is likely that the abnormality is a trait-marker for depressive illness and may be useful in practice as a predictor of vulnerability to this disease. The tyramine test is superior to the dexamethasone suppression test in both sensitivity to, and specificity for,

endogenous depression. Patients who responded to tricyclic antidepressants had significantly lower pretreatment tyramine excretion values than non-responders.

Brief dynamic psychotherapy

Intensive short-term dynamic psychotherapy: trial-therapy model of initial interview as a selection criterion

Dr H. Davanloo, McGill University, Canada

Two major factors leading to the extreme difficulty and great length of dynamic psychotherapy are *resistance* and *transference*. In Davanloo's technique it is possible first to hasten the onset of these two phenomena and then to meet them head on and resolve them, in such a way as to gain direct access to the unconscious within a single interview.

The process begins with pressure towards the patient's avoided feelings. The patient responds with an increase in resistance, which takes the form of a series of defences. In contrast to traditional methods of dynamic psychotherapy, these defences are not *interpreted* but *challenged*. The result is a rapid rise in transference feelings which the patient wishes to avoid, resulting in a further intensification of resistance. The resistance, now in the transference, is challenged in the same way as before. Eventually, the defences become exhausted and the patient is able to experience his transference feelings directly and to acknowledge them to the therapist.

The effects are marked and dramatic. There is a major drop in tension and a mobilisation of the therapeutic alliance and the patient often makes a communication that throws light on central aspects of his neurosis.

At this point, and not before, the therapist begins to use the main intervention of traditional dynamic psychotherapy, namely interpretation. The residual resistance is systematically analysed by interpretation of the two triangles: defence, anxiety and hidden feeling (the 'triangle of conflict'), and current, transference, and past relationships (the 'triangle of person'). This leads eventually to a phase in which for the time being resistance is almost completely in abeyance and the therapist can achieve direct access to the unconscious without further reference to the transference. He is then able to bring the patient to the experience of some of the most painful or anxiety-laden feelings that lie behind his neurosis, which sets the whole therapeutic process in motion.

All this can be achieved in a single initial interview lasting from 1½ to 4 hours. As a result the patient's whole psychic system is permanently loosened; and any patient who responds in this way can be selected with confidence for intensive short-term dynamic psychotherapy in which exactly the same technique is used. Thus the response to this form of *trial therapy* constitutes the main selection criterion. The number of sessions required varies from 1 to 10 for simple symptomatic neuroses, through 10 to 20 for more complex cases, to 20 to 40 for character disorders of increasing severity and complexity.

Care of the chronic patient in the community

Family management of mental illness: Clinical, social and economic benefits

Dr I. R. H. Falloon, Buckingham Mental Health Service

The role of the family unit in the care of the chronically ill in the community is threefold, providing supportive

housing, providing informal nursing care, and providing stress management. The capacity of families to meet such extensive demands varies considerably, with very few able to perform such a role without substantial training coupled with long-term professional assistance. The family stress associated with the shift towards community management of all mental illness is often extreme and likely to reduce the long-term viability of this key community resource.

Current approaches to the family management of schizophrenia have focused on enhancing the efficiency of the family in the management of stress. This has included the everyday stresses encountered by the index patient and his or her family caregivers, family members' stresses independent of the index patient and stressful life events that impinge upon all family members. It is assumed that for any family to cope with a member who has developed a chronic or recurrent illness exceptional efficiency in problem resolution is needed.

The efficacy of one approach to family management that includes optimal medication, education about schizophrenia, behavioural family therapy and specific coping strategies is presented. Significant benefits have been found in terms of clinical, social and family morbidity. These benefits are discussed as well as the costs to the community of family care.

A case management programme for difficult-to-treat patients *Professor L. I. Stein, University of Wisconsin Medical School, USA*

There is general agreement that persons with chronic mental illness living in the community require 'case management'. This paper reviews the conceptual foundation for case management, describes its functions and discusses several case management models. One model discussed in greater detail is one that has been researched and found to be effective in working with difficult-to-treat patients. This patient population shares some or all of the following characteristics: an unwillingness to regularly come in for services, poor medication compliance, a need for structured daily activities, a poor ability to self-monitor and frequent crises. The special case management programme developed to serve these patients is staffed by a multidisciplinary team that operates two shifts per day, seven days a week. Much of their activity takes place out in the community rather than in the office. Patients are carefully evaluated and monitored, barriers to community tenure are identified and worked with. No time limit is established—patients are worked with for as long as they need the programme—this may be for a lifetime. Results clearly show a decrease in symptomatology, an increase in stability and a marked decrease in use of the hospital.

Long-term patients in the community. An Italian experience *Professor Michele Tansella, Istituto di psichiatria, Verona, Italy*

The Italian model of community psychiatry, as prescribed by the 1978 psychiatric reform, is described. Three distinctive features of this model are worthy of note. First, the phasing out of mental hospitals was intended to be a gradual process—by means of a block on first admissions and subsequently on all admissions—rather than an abrupt deinstitutionalisation of chronic patients. Secondly, the

new services were designed to be alternative rather than complementary or additional to mental hospitals. Thirdly, it is hospital psychiatry (which, with the passage of time, is increasingly located in general hospitals rather than in mental hospitals) which is considered complementary to community care, and not vice versa.

Evidence collected in areas where the reform has been correctly implemented indicates that the 'new' community services are able to cope with the problems presented by the whole range of psychiatric patients resident in the catchment area. Moreover case-register data from three of these areas (Pavia, Portogruaro and South Verona) show that most of the patients are treated outside the hospital only. The rates of long-stay patients (≥ 1 year in hospital) have been decreasing over the years in all three areas, while rates of 'new' long-stay are very low and there is no evidence that such patients are accumulating in any of the three areas. The South Verona experience will be described in some detail. South Verona is an area of 75,000 inhabitants where a comprehensive and well integrated community psychiatric service has been set up and organised according to the provisions of the new law. In the organisation of this service, effort has been directed towards ensuring therapeutic continuity, long-term support and care to patients and their families, as well as integration between different kinds of intervention (made by the same team). In South Verona while the number of long-stay patients is decreasing, the number of 'long-term users of psychiatric services' (those in contact with some form of psychiatric service—not necessarily the same one—for a year or more without a break of more than three months) is increasing. The results of a two-year follow-up study of a cohort of long-term patients is presented.

Schizophrenia and the quality of life

Professor P. R. A. May, University of California, USA

A limitation of our current concepts of treatment is that we have tended to focus on rather narrow concerns such as relief of symptoms and return to community living. The time has come to think of other things, and particularly of quality of life (QOL). As an offshoot of some other research, we came to consider QOL systematically. Life is more than doctors, pills and symptoms, more than psychotherapy or having your behaviour modified by the experts. It has many aspects. We each value them differently.

Originally we identified 16 main components of quality of life: (1) physical health; (2) mental health; (3) material resources; (4) education; (5) employment; (6) recreation; (7) daily services; (8) welfare services; (9) non-material: art, relationships; (10) knowledge/education; (11) safety and security; (12) beauty of nature, (13) inner QOL: spiritual, religious, contentment; (14) national esteem; (15) national defence; (16) peace.

Later we identified 12 main areas that seemed suitable for assessment of the QOL of schizophrenic patients: (1) housing; (2) material; (3) environment; (4) safety; (5) travel and communication; (6) physical and mental health; (7) work; (8) leisure; (9) education/knowledge; (10) relationships; (11) inner experience; (12) religion.

These were set out in a checklist from that could be filled in by an interviewer to portray the patient's QOL from either the patient's or the staff's or the family's view of it

This proved to be a useful tool for identifying areas of a patient's life that needed attention. In subsequent work, Malm and Skantze have rearranged the items as a questionnaire to be filled in by the patient. It is clear that many aspects of patients' QOL are not under the control of the health care system at all. We need to point out to other agencies that they too have some responsibilities for the patient's QOL and that we expect them to do something about it.

Aggression

Premorbid personality of depressive, bipolar and schizophrenic patients, with special reference to suicidal issues

Professors Jules Angst, Psychiatric University Hospital, Zurich, Switzerland and Paula J. Clayton, University of Minnesota, USA

The personalities of 6,315 Swiss conscripts of the army were assessed in 1971 by the Freiburg Personality Inventory (FPI), together with social attributes and consumption of tobacco, alcohol and drugs. New factor analyses of the FPI produced three scales, extraversion-introversion, autonomic lability and aggression. Up to 1983, 185 psychiatric patients were identified who were treated as in-patients or out-patients in the same geographic area. A sub-sample of 87 patients were chosen for a blind diagnostic study applying Feighner criteria to the records. Their premorbid personalities are compared to controls from the same group. The results are preliminary, the diagnostic groups are small.

The bipolar patients do not deviate significantly in any personality dimension from the controls. They differ significantly from the unipolar depressives by a lower aggression score. Unipolar depressives score high in aggression and in autonomic lability. The same is true for the socio-paths. Aggression scores are also high in those who committed suicide or died by accidents. Independent of the diagnostic classification, subjects with suicidal attempts score high in aggression, whereas subjects with suicidal ideation score low in aggression.

Biological aspects of suicide and aggression

Dr S. A. Montgomery, St Marys Hospital, London

There are many cultural factors which may affect suicide and suicidal behaviour: religion, war, economic factors—and the rates vary widely from country to country. In spite of this variation there has been a consistent demonstration of a relationship between a biochemical measure and suicidal behaviour. A number of centres in different countries have now reported a significant association between low levels of 5HIAA, the serotonin metabolite in the CSF, and a history of suicidal behaviour. In those studies that have reported HVA, a significant relationship between low levels and suicidal behaviour may also be seen. These studies were originally conducted on depressed patients. Subsequent studies on difficult US naval personnel indicate a similar relationship in personality disorders. In the centres that graded the violence of the suicidal act it would appear that violent suicidal acts appear more particularly associated with low 5HIAA and HVA. In the US naval personnel a history of aggression correlated with CSF 5HIAA. A review of intervention studies demonstrates the failure of general psychiatric follow-up, or social or psychotherapeutic

measures to lower the repeat rate. The significant reduction in suicidal behaviour seen on a low dose neuroleptic suggests that possible pharmacotherapy should be investigated more thoroughly.

Impulsivity and the serotonin system

Professor J. J. Lopez-Ibor Jr., University of Alcalá de Henares and Ramon y Cajal Hospital, Madrid, Spain

Biological research in affective disorders has evolved in recent times from the research of neurochemical substrates of the disease or of its clinical subtypes into the correlation of laboratory data and specific symptoms or behaviour patterns ('target symptoms'). The serotonin system has been shown to be involved in suicidal behaviour not only in affective disorders but in schizophrenia and personality disorders. Serotonin has also been claimed to be involved in aggressive behaviour, even in non-psychiatric cases, in bulimia and other disorders. It has been suggested that the common link of these and other symptom patterns is a lack of adequate control of impulsivity. But correlations between behaviour patterns that are not specific to a disorder or diagnostic category and that may be present in normal psychology as traits of individual coping styles, put forward very important methodological problems.

The psychoanalytic theory of aggression

Professor J. Sandler, University College, London

The notion of aggression is an important one in psychoanalysis, but there is no one psychoanalytic theory of aggression. Freud developed several theories of aggression during his psychoanalytic lifetime, and further psychoanalytic formulations have been made since. At present there are psychoanalysts who see aggression as a fundamental drive which parallels sexuality, and who postulate the existence of aggressive as well as sexual energies as motivating forces in mental functioning. Other psychoanalysts adhere to and amplify Freud's theory of the death drive. There are also those who reject the idea of a primary aggressive drive completely, and this group overlaps with those who do not accept the energy model in psychoanalysis but incline more towards a systems theory approach.

A short historical overview shows how very different Freud's theories of aggression were. These range from the idea of aggression as a 'self-preservative' drive to that of a primary death drive. There are a number of important distinctions which are relevant to the psychoanalytic approach to aggression. These include the distinction between aggressive behaviour and unconscious aggressive impulses. The view is put forward that emphasis should be placed on the consideration of the aggressive wish as opposed to the aggressive drive, as many different stimuli, both internal and external, can evoke an aggressive wish. The relation of the aggressive wish to effects such as anger has to be reconsidered, and wish-fulfilment needs to be looked at from a different point of view than that of energy discharged. The particular psychoanalytic formulations put forward in this presentation have important clinical implications, some of which are touched upon.

The symptom of irritability and related concepts

Dr C. M. Taylor, St James's University Hospital, Leeds

The symptom of irritability is related to the concepts of anger, hostility and aggression. When the relationship between irritability and the affects of anxiety and

depression is explored in neurotic patients, irritability behaves as if it were an independent variable. This suggests the possibility that it could represent a distinct and separate mood state. The different aspects of this state are explored and it is suggested that this could represent an altered state of autonomic reactivity. Some relevant literature is described and the nosological status of irritability is discussed.

The psychology of malignant disease

Bereavement and cancer: Results from the OPCS longitudinal study

Dr D. R. Jones, St George's Hospital Medical School, London

The results of initial analyses comparing cancer registration and death rates following widow(er)hood with corresponding age-sex specific rates in a large sample representing the whole national population have already been reported.¹ Data were derived from the OPCS Longitudinal Study, in which routinely collected data on cancer registrations, deaths and deaths of a spouse occurring in a 1% sample of the population of England and Wales in the period 1971-1981 are linked together and with the 1971 Census records of sample members. There was little evidence of an increase in cancer registration rates following widow(er)hood and only a weak suggestion of increased cancer death rates, offering little support for the hypothesis that stress (of bereavement) is implicated in the aetiology of cancer.

In this paper, patterns of post-widow(er)hood cancer morbidity and mortality are explored in several more detailed analyses. In particular, the dependence of mortality ratios on factors such as sex, age, social status, economic activity and measures of social and familial support, including household structure and family size, are investigated.² In general, the differentials observed are similar to those to be seen in general mortality.

Variations of mortality ratios with time since bereavement are also considered. Although cancer mortality ratios in the period immediately following widow(er)hood are much less elevated than those for other causes such as accidental and violent deaths, there is some evidence of excesses of cancer deaths after longer periods, e.g. an excess of about 50% from breast cancer three or more years after widowhood. Other aspects of post-bereavement cancer morbidity and mortality analysed include the patterns of causes of death in spouse pairs. Concordance of cancer deaths in spouse pairs lies close to the expected value; in other words, there is no evidence that cancer is the cause of death of both members of a spouse pair more often than is to be expected.³

Psychotherapy with cancer patients

Dr Pamela Ashurst, Royal South Hants Hospital, Southampton

A diagnosis of cancer constitutes an emotional crisis for the individual concerned, and for his/her immediate family, which is frequently aggravated by the management and

treatment of the condition. Cancer patients are under a special and severe form of stress and the price of survival may be considerable. Cure, if possible, must be the aim of both patient and clinician; nevertheless the good physician must have a concern also for his patient's *feelings* about the disease and its treatment. The severity of the condition, the nature of the treatment and the possible consequences for body image and function, and the broader psychosocial concerns which may deeply affect the quality of life, will all influence the patient's reaction.

The individual with cancer faces his own mortality in a very special way, and other life issues may be brought into sharp focus when physical survival is under threat. This paper draws on clinical experience of psychotherapy with patients in whom cancer has been diagnosed.

Tardive dyskinesia

Non-neuroleptic aspects of tardive dyskinesia

Drs D. J. King, A. Wilson and S. J. Cooper, The Queen's University of Belfast and Holywell Hospital, N. Ireland; Drs J. Waddington, Department of Clinical Pharmacology, Royal College of Surgeons in Ireland, Dublin and H. A. Youssef, St Davnet's Hospital, Monaghan

It has been difficult to demonstrate a relationship between the presence of tardive dyskinesia (TD) and the history of neuroleptic drug exposure in clinical studies.¹

This report summarises three surveys of TD in chronic schizophrenia in two hospitals. The first included 68 patients (mean age 65.1 years), 28 (41%) of whom had TD according to the criteria of Schooler and Kane.² The second and third studies looked at 16 patients (mean age 44.4 years) who had previously had CT scans as part of another study. Four (25%) of these had TD on both occasions (persistent TD).

No association could be demonstrated in any of these three studies between either the prevalence or severity of AIMS and any measure of exposure to neuroleptic drug treatment (age of onset, duration, mean daily dose, life-time intake, or current dose). Negative symptoms, however, (mutism and affective blunting) and cognitive impairment were consistently associated with TD. Patients with persistent TD had significantly larger cerebral ventricles (VBR) than those who did not ($P < 0.05$). AIMS scores were also highly correlated with the presence of neurological soft signs ($r_s: 0.914, P < 0.01$).

Thus chronic schizophrenic patients with persistent TD are characterised by negative symptoms, cognitive impairment and large VBRs. Neuroleptic drug exposure would appear to be neither a necessary nor a sufficient explanation for TD in these patients.

Tardive dyskinesia: Which patients are at risk?

Dr T. R. E. Barnes, Charing Cross Hospital & Westminster Medical School, London

The majority of patients receiving antipsychotic drugs do not develop tardive dyskinesia. The identification of factors contributing to individual vulnerability to this condition

should be of help in its prediction and prevention. With a paucity of long-term, prospective studies testing the predictive value of both treatment variables and patient variables of possible relevance, evidence from cross-sectional and retrospective studies, and short-term follow-up investigations, of tardive dyskinesia is examined. Almost invariably, a statistically significant relationship has been found between the main treatment variable, the administration of antipsychotic drugs and risk of tardive dyskinesia, although no such relationship has been convincingly demonstrated for dose, duration or type of drug. There is little evidence to implicate the chronic use of anticholinergic agents, or prolonged hospitalisation, as important risk factors. The patient variable predicting, most consistently, the appearance, severity and persistence of the condition is advancing age. Other patient variables that may be associated with an increased likelihood of developing tardive dyskinesia include a susceptibility to drug-induced parkinsonism and akathisia, a history of brain damage and a diagnosis of affective disorder. Also, recent findings, including preliminary data from our own work (Barnes, T.R.E. & Liddle, P.F., unpublished), suggest a significant positive relationship between the presence of negative symptoms in schizophrenic patients and tardive dyskinesia.

Measurement of extrapyramidal symptoms and involuntary movements by electronic instruments

Professor P. R. A. May, University of California, USA

Abnormalities of the extrapyramidal system (EPS) and involuntary movements (IM) such as tremor, rigidity, and dyskinesia are of great importance in psychiatry. They occur in a variety of organic brain disorders and, even more importantly, as side effects from neuroleptic drugs, in particular, dyskinesia, dystonia, akathisia, akinesia, rigidity, and lack of emotional expression. These create misery and suffering for the patient, and the problem has serious implications for all patients who are receiving neuroleptic medication.

A major problem is that EPS and IM are difficult to measure. Reliance has been placed largely on rating scales that are heavily dependent on the rater's subjective judgement, and whose inter-rater agreement leaves much to be desired. Measuring instruments have been used in some research studies, but the methodologies in their present form are not suitable for general use. Hence, research and clinical work in this area have been limited by lack of precision.

During the last eight years, the investigator has initiated development of a battery of prototype instruments to measure and analyse EPS-IM directly, objectively, non-intrusively, and with a high degree of precision, that are easy to administer, and that require only a relatively low degree of co-operation from the subject. Substantial progress has been made. Prototype instruments (systems) have been developed to measure tremor and involuntary movement of various kinds in different parts of the body, in particular, resting, sustention and intention tremor; facial, leg and trunk, and general body movement; and blink rate. Can examples and pilot data indicate that such equipment would be useful for early recognition, accurate diagnosis, long-term monitoring, documentation, to guide appropriate adjustments in drug therapy, and to stimulate staff education in this area?

With any laboratory test, the ideal system should combine the skills of the clinician with the capability of a machine. A machine can measure the degree and frequency of movements better than a skilled clinician. But a clinician is still essential to classify/identify the type of movement and to differentiate artifacts. In other words, the machine's function is to assist and extend the capabilities of clinicians, not to replace them.

Caring for the carers

The contribution of the psychogeriatric service from the carer's viewpoint

Dr P. Coleman, University of Southampton

As part of an investigation into the factors underlying effective collaboration between services for the elderly mentally infirm, interviews were carried out with a cross representation of staff in social, geriatric and psychiatric services in two health districts, one with and one without a specialised psychiatric service for the elderly. These indicated the contribution of the psychogeriatric service to the education of other professionals, and improved liaison between them, as well as the provision of a more effective service to patients and their carers, with a prompt response to referrals and reliable follow-up and support. Interviews with a small group of carers of demented elderly people referred to services provided evidence consistent with this evaluation, but also indicated points for further investigation. These included the counselling role of the community psychiatric nurse, the need for the right kind of day care, and the value of relief admissions.

Sitting service for demented patients

Dr H. P. Rosenyunge, Moorgreen Hospital, Southampton

In 1983, a sitting service for the elderly patients suffering from dementia was set up with the aim of offering home based support for the relatives living with them. A salaried, part-time co-ordinator recruited and matched paid sitters with the cases referred by the psycho-geriatric unit. Finance was obtained from Joint Funding and was administered by the local branch of MIND. At the end of the three year pilot study, 99 patients had received sitting service support. This paper describes the setting up of this service, the types of patients and families receiving support. An attempt to analyse its effect on the families studied and on the psychogeriatric service is made. A reduction in long-stay bed usage is shown.

Caring aides as an extension of the community psychiatric nursing service in Bournemouth and East Dorset

Drs M. A. Rowton-Lee and C. J. H. Williams, St Ann's Hospital, Dorset

Caring aides (patient aides) are unqualified persons recruited locally to support and relate to the community psychogeriatric nurses caring for ESMI patients in the community, concentrating mainly on those with brain failure. They may or may not have previous nursing experience: personality factors are important—lots of common sense and a liking for looking after people.

Bournemouth and East Dorset is a district with a high loading of elderly people. In a population of approximately 400,000, nearly 25% are over the age of 65. The projected population over the age of 75 is 11% compared to 6.8% for

the national average. A large proportion of the elderly in Bournemouth and East Dorset have migrated into the area on retirement away from their extended family and live alone and unsupported. The district is under-resourced in terms of beds available for the care of Brain Failure and this falls well below the recommendations in *Priorities for Health and Social Services in England* (HMSO 1976). Based on a planning norm of 2.75 beds for 1000 of the population over the age of 65, the district was undermanned by 100 beds.

It is with this background that the concept of caring aides, also known as patient aides, was developed. The number of beds available was simply inadequate. The community psychogeriatric team had been developed and its effectiveness was therefore extended by the addition of the patient aides. In 1977, Christopher Williams, general practitioner and hospital medical practitioner, prepared a paper for the Dorset Area Health Authority *The King's Park Hospital at Home—An Option for the East Dorset Health Care District*. In it he reviewed the application of the 'hospital at home' concept to the needs of patients with brain failure being cared for in the community. This coincided with the realisation of the clinical team of which he was a part that there was a need to extend the caring capacity of the domiciliary team. The notion of caring aides attached to the community psychogeriatric nurses and through them to the clinical team was developed and provided a substitute for the extended caring tribal family.

A pilot project was established in 1981 and the work of four patient aides, two in Bournemouth and two in Poole was monitored with the help of the Health Services Organisation Research Unit at Brunel. The report on a year's work *The Extended Care Project for Psychogeriatric Patients*, validated the view already held at team level that the patient aide was a valuable extension to the community team, increasing the quality of care for dementing patients in the community and that they improved the quality of life of both patients and carers.

Patient aides receive in-service training. Their job description is flexible and allows them to cross the artificial boundaries of Health and Social Services. It is important that they co-operate with home helps, concentrating more on the care of the person rather than the care of the environment. In practice if the selection of the right kind of person has been carried out properly, this interaction takes place without fuss. Difficulties mostly occur if administrators define the job too narrowly, the concept works best with flexible action and positive thinking. Lines of communication are important and the patient aide is responsible to and relates with community psychogeriatric nurses, who themselves maintain important lateral links with the Social Services and primary health care teams. The close contact between the patient aide and the clinical team allows the patient aide to feed in information rapidly about a deteriorating clinical situation.

Patient aides were shown to perform 'basic looking after work'. This included attention to physical comfort (including toileting); physical safety, psychological comfort (including structured social stimulation and orientation to personal and social reality), attention to feeding as well as the ordinary ministrations which are needed when an individual cannot look after himself. Attention to physical comfort may include giving a bath or tidying up a room. Attention to feeding may include actual feeding or helping

a patient to prepare food, either as a part of seeing that patients get food or as a part of a programme of rehabilitation, social stimulation may range from chatting to therapeutic reminiscing or even taking them to a pub for a drink. Duties include help with incontinence aids, facilitating the hospital to community laundry service, supervising medication and assisting with shopping, collection of prescriptions and pension, payment of bills and providing a granny-sitting service to enable relatives to get 'time off'.

Assessment of the project leads us to believe.

- (a) That the length of time for which a patient can remain out of institutional care is extended and the quality of life is improved.
- (b) The quality of life for caring relatives and supporting friends is also improved and not only is there increased willingness for them to continue to support but support in the community becomes the preferred form of management.
- (c) Other supporting services are prepared to continue to support the patient at home and tend to produce more positive input (responding to increased support by the clinical unit) instead of withdrawing their services because they feel overwhelmed, isolated and in difficulties.
- (d) Crises are averted and coped with
- (e) The expertise of the in-patient unit becomes available to a greater number of the elderly mentally infirm, and can be, at least theoretically, extended to all. Because people are being managed in the community instead of being institutionalised, the unit beds and particularly the assessment beds are available to patients (all of whom are equal number 1 on the waiting list) to come in when they are ill, or there is a crisis, and in-patient care is therefore available when most needed.

The concept of the caring aide was not devised to be a cheap alternative to inpatient care, but it has in fact proved cost effective. The project demonstrated that the service provided at relatively little financial cost enormous benefits to patients, relatives and other caring agencies. Patient aides experienced considerable job satisfaction. Often important bonding occurred between aides and patients and families they were supporting. Born out of necessity, helped by the caring aide, the community support became the caring service of choice for brain failure.

Support group for carers

Mr N Moffat, Branksome Clinic, Poole

An evaluation is provided of the setting up and running of a support group for relatives of patients with dementia.¹ The first stage reports a survey of known carers in Britain. Following this a survey of the needs of local carers was carried out and a 10 week programme chosen from this needs questionnaire. The initial evaluation involved 17 carers who were interviewed before and after being on a waiting list or participating in a support group. Participants provided positive feedback on all meetings. There were non-significant trends for a reduction in carers' expressed need for information, and in scores on the General Health Questionnaire. There were no significant changes in the Ways of Coping Questionnaire, and changes on the Personal Questionnaire were more related to respite care than to attendance at the support group. The small sample size of the initial study is recognised and the results from a further sample is reported. The formation of a monthly

outing for carers is described as a follow-up to the short-term structured groups.

¹TRIGG, A. (1984) Evaluation of a structured support group for relatives of patients with dementia. BPS Diploma.

Short papers

Attempted suicide by deliberate self-poisoning in four immigrant groups

Dr J. Merrill, All Saints Hospital, Birmingham

Rates and characteristics of deliberate self-poisoning in four immigrant groups, Asian, West Indian, Irish and Scottish were compared with those of white English-born resident in an inner-city area of Birmingham. Irish and Scottish-born were over-represented in all age/sex groups. Asian and West Indian males and older females were under-represented. Substantial differences in the characteristics of self-poisoning were found between immigrant and control groups. Alcoholism was increased in Irish and Scottish groups. Asians frequently suffered from marital problems and culture conflict. Teenage pregnancy and separation from parents in childhood were more common in West Indians. The relevance of the findings to the assessment and management of self-poisoners is discussed.

Deliberate self-harm: correlates of suicidal intent and severity of depression

Drs G. O'Brien, A. Holton, K. Hurren, L. Watt and F. Hassanyeh, Nuffield Unit for Child Psychology and Psychiatry, Fleming Memorial Hospital and Royal Victoria Infirmary, Newcastle-upon-Tyne

It is well-recognised that people who commit acts of deliberate self-harm vary widely in their suicidal intent and severity of depression. This study sought to identify characteristics which correlate with suicidal intent and depressions and also to assess how well some of the available rating scales correlate with each other, in this population.

Ninety-eight consecutive referrals for deliberate self-harm were given a semi-structured clinical interview. Cases were also assessed on Spitzer's Research Diagnostic Criteria (RDC), on the Pearce Suicide Intent Scale, on the Hamilton Depression Scale and on the Newcastle Diagnostic Scale for Depression. In addition, the interviewing clinician made a clinical decision on diagnosis.

The findings showed that the RDC 'cases' had higher suicidal intent and were more significantly depressed on Hamilton Scale than 'non cases'. Diagnosis of 'Endogenous' type depression on the Newcastle Scale had a high correlation with Hamilton Score and a moderate correlation with suicidal intent. In addition to high correlation with RDC 'caseness' and Newcastle diagnosis of endogenous depression, there was a high correlation of Hamilton Score with suicidal intent. With respect to early parental loss or bereavement, there was no significant correlation with any of the above measures.

Rape: The behavioural and psychological sequelae in the partners of the victims

Dr A. W. Bateman, The Royal Free Hospital, London

The plight of the rape victim has been given increasing

attention over the last decade but very little emphasis has been placed on the reactions of their partners. Over the last year the partners of rape victims referred to a victim support scheme have been interviewed and counselled. A characteristic response by victims' partners has emerged.

The liaison with a voluntary community organisation will be discussed and the behavioural and psychological changes in the male partner of the rape victim described in detail. Illustrative cases are used to show how the psychological changes in a victim's partner may not only have severe consequences for the individual but also interfere with any help offered to the victim.

Delusional and non-delusional depression in late life: Evidence for district subtypes

Dr R. C. Baldwin, Manchester Royal Infirmary

The study tested the hypothesis that delusional and non-delusional depressive illness are distinct clinical entities in late life and carry different prognoses. From a larger retrospective study (in press) aimed at clarifying the long-term outcome of major depression in old age, 24 patients were identified with late onset delusional depression and were matched to 24 late onset non-delusional controls with depression. At the index admission delusional cases were significantly more depressed, were hospitalised for longer and received significantly more by way of physical treatments, especially ECT and major tranquilisers. However, the clinical status at discharge was no different from the controls, neither was the outcome, over a period of between 42 and 104 months, in terms of relapse rates, deaths and overall prognosis for depression. One striking difference was the finding that whilst relapses in the delusional group were frequently characterised by further delusions, this never happened for the non-delusional controls. The latter finding, coupled with the severity and treatment differences mentioned, suggests that the view already widely held for younger patients and based on similar evidence, namely, that delusional depression is distinct from non-delusional forms, is also true for the elderly. These findings do not, however, support recent work which suggested a very poor prognosis for delusional depression in late life.

Personality and emotional disturbance in rheumatoid arthritis

Drs F. McGregor and P. Jauhar, Duke Street Hospital, Glasgow

One hundred and eighty-two patients with rheumatoid arthritis were studied to examine the distribution of personality scales and the incidence of psychiatric morbidity and to explore the effects of pain, disability and serology upon these indices. All the patients completed a set of questionnaires including the Eysenck Personality Questionnaire, the Hospital Anxiety and Depression Scale and the General Health Questionnaire. Seventy-six patients were interviewed using the Clinical Interview Schedule. Patients were more likely to be introverted than population norms, women were more likely to produce socially desirable results and men were more likely to have a tendency to neuroticism and were significantly more likely to be emotionally disturbed. Pain and disability were found to be associated with psychological disturbance in women, but only disability was an important factor in men. The importance of other factors in these findings is discussed.

Peter Scott Scholarship 1984. Help for the victim of violence: are there lessons to be learnt from American rape crisis programmes?

Dr G. C. Mezey, The Maudsley Hospital, London

I have recently completed a study at the Institute of Psychiatry investigating the effects of rape on the victim. As a result of this work, I was funded by the Peter Scott Scholarship to visit hospital-based rape crisis programmes in the United States earlier this year. This paper is the outcome of the visit and describes how the care of rape victims in the States has become a very integral part of the total Health Service provided by hospitals.

The American Rape Programmes were set up in general hospitals in the early 1970s (McCombie et al 1976)¹ and have since proliferated in number, so that almost every major city now has at least one such programme operating. The programmes are run by a multidisciplinary team and provide for the physical, emotional as well as the practical needs of the victim. They function for 24 hours a day and provide both acute and follow-up services.

Staff training in all disciplines reflects the importance given to the concept of 'psychic trauma'. Victims of violence are seen as having as legitimate a claim to the health services provisions as patients who present with 'physical' emergencies. The paper describes the functioning and set up of rape crisis programmes in one large city in N America: Boston. It shows how these programmes link up with other, 'community' based services, with the police and legal bodies. I describe some of the recent laws passed relating to rape victims, perhaps a reflection of the increasing seriousness with which this problem is viewed. Finally, I discuss some of the current victim research that is being done by the Boston groups and the implications this may have for our work as psychiatrists in Britain.

¹McCOMBIE, S., BASSUK, E., SAVITZ, R. & PELL, S. (1976) Development of a medical centre rape crisis intervention programme. *American Journal of Psychiatry*, 133, 418-424

Opiate withdrawal: A comparison of in-patient and out-patient programmes and of preferred versus random assignment to treatment

Drs A. Johns, M. Gossop and Mrs L. Green, Bethlem Royal Hospital, Kent

This prospective study looks at the relative effectiveness of an in-patient and an out-patient withdrawal programme for opiate addicts. Addicts were more likely to achieve a drug-free state on the in-patient withdrawal programme than on the out-patient scheme: success rates were 18% (in-patients) versus 17% (out-patients). This in-patient/out-patient difference could not be attributed to pre-treatment, drug-related factors, nor to social or psychological differences between the groups. The results have clinical and policy implications for the treatment of opiate addicts and some of these are discussed.

Factors associated with compliance in the follow-up treatment of alcoholism

Dr B. Fleming, Shaftesbury Square Hospital, Belfast and Professor Stuart Lewis, Queen's University, Belfast

This study set out to examine factors associated with compliance in the follow-up treatment of alcoholism. Twenty-five patients who dropped out of treatment within six months were compared with 25 patients who completed

a two-year treatment programme. The two groups were compared for socio-demographic factors and personality traits using the EPI and Cattell 16PF. Personality traits did not discriminate between the two groups. However, as in previous studies significant correlation between low socio-economic class and dropping out of treatment was found. Marital instability and a family history of alcoholism also tended to correspond with dropping out of treatment, although this tendency was not statistically significant.

High section 136 admission rates: A challenge to community psychiatry

Drs T. Fahy, The Maudsley Hospital, London, D. Bermingham, St Thomas' Hospital, London; J. Dunn, Tooting Bec Hospital, London and P. Joyce, St Augustine's Hospital, Kent

Section 136 admission rates to St Augustine's Hospital, Canterbury and Tooting Bec Hospital, London were reviewed for the two-year period following the introduction of the 1983 Mental Health Act. Rates of three and six times the national average respectively were detected. There were many similarities between the groups despite major demographic differences. Factors influencing admission rates differ between regions. The St Augustine's group was surprisingly heterogeneous for several variables. Absence of out-of-hours social work support was judged to be a crucial determinant of their high rate. By contrast the Tooting Bec sample were heavily weighted for a large number of variables including sex, age, ethnic origins and certain diagnostic categories. In both groups over one third of patients received a diagnosis which was not classifiable under the Mental Health Act definition of a mental disorder. An intensive community based response to the problem of high Section 136 admission rates would be well positioned to tackle important aetiological factors and may contribute to reduce the number of such admissions.

The micro-computer in rehabilitation

Dr A. McDonald, The State Hospital, Carstairs

The rehabilitation of schizophrenic patients is one of the major problems of psychiatry. The illness renders a person peculiarly susceptible to stress and unable to participate fully in day-to-day relationships and living. For many, thought disorder and lack of motivation prohibit the full use of their intellect when more florid psychotic symptoms may have disappeared.

This study sought to examine the use of a micro-computer by long-term schizophrenic patients as a means to motivate them, to allow them to function at an appropriate intellectual level and to facilitate interaction with other people. Although no such previous work has been done this multi-disciplinary project drew heavily from experience in the field of special education.

The use of the computer by 11 chronically ill, several incapacitated, schizophrenic patients is described. No particular type of programmes were found to be of preference but it was crucial that a therapist shared the experience with the patient. Most important in its use as a facilitator is the concept that the mastery of the computer is not an end in itself but rather a rehabilitative aid in the schizophrenic's relationship with other people. Whilst some delusional interpretations were expressed in relation to the computer it did not become an object of paranoia and showed itself to be a good motivator, facilitating interaction with other

patients and staff which generalised beyond the computer setting. Further research would seem to be indicated although the progress obtained does not lend itself readily to quantitative assessment.

Early mother/baby contact: positive consequences

Dr de Wet S. Vorster, Plymouth Nuffield Clinic, Plymouth
Winnicott stressed the 'holding' of the infant as of great import especially relevant to the more severe psychiatric illnesses in later life. A few prospective studies have indicated the import of early mother/baby contact concerning later healthy psychobiological development. Klaus indicated the import of the first half hour postbirth contact and follow up at ages three and five years showing a better mother-child relationship. Attempts to replicate these studies have not always succeeded; the improvement in the experimental group (close contact) may have been due to other factors. However, de Chateau's work revealed no major differences in personality characteristics of mothers in both control and close contact groups.

As studies have involved small numbers, a larger sample was pursued in the study described. Findings from the present ongoing study of 300 mother/baby pairs at the six week developmental testing will be presented.

An early mother/infant contact questionnaire was completed by clinical medical officers. Key questions included duration of contact postbirth and in first months, most successful cry cure, and possible relationship between early contact and subsequent symptoms in mother and baby. Results mothers and babies who had 20 minutes or more contact postbirth presented fewer problems e.g. crying, feeding disorder, at age 6 weeks, 10 minutes or less contact presented the same percentage of problem behaviour as for those separated at birth; more problems occurred in the latter two groups to a significant degree statistically.

To verify the memory of mothers concerning the infant contact questionnaire represented by medical officers at six weeks, further work has included a mother/baby bonding chart completed by midwives on a second group of 300 mother/baby couples recording the length of time the baby was in proximity to mother immediately postbirth, as well as recording Apgar ratings and obstetric factors, destination of baby after leaving mother and reasons for interruption of holding time. Babies' response to holding, amount of crying and type of feeding were recorded. Results indicated that only a third of mothers and babies were together for 20 minutes or more; crying was not frequent in this group of babies; breast feeding occurred in the same percentage of both groups and obstetric factors failed to account solely for different holding time. Results of later follow-up are presented.

Television violence and childhood aggression: The field experiments

Drs K. D. Gadow and J. Sprafkin, State University of New York, USA

For over two decades the viewing of television violence has been implicated as playing a role in childhood aggression either as an etiological mechanism, an environmental stimulus that exacerbates symptoms, or both. Although laboratory studies are generally interpreted as providing overwhelming support for these notions, actual acts of symptomatic behaviours are typically not recorded in these studies. Rather, child behaviour is generally evaluated with

regard to reactions toward inanimate objects or playing games. The more ecologically valid field experiments (i.e., conducted in natural settings) are also considered to support the aggression-induction hypotheses. A careful reading of the 15 field experiments conducted to date (four of which were recently completed by our research team) provides only weak support for this interpretation. In fact, the majority of these studies show that viewing non-aggressive material is generally more aggression inducing than viewing aggressive shows. Moreover, our own research on emotionally disturbed (conduct disordered) and learning disabled children has clearly shown that watching aggressive television programmes is *not* more likely to exacerbate the symptoms of conduct disorder than non-aggressive content. Interestingly, while existing research efforts do not appear to support the aggression-induction hypothesis, they do indicate that television is not a neutral medium. Compared with baseline levels of antisocial behaviour, many studies show that, regardless of content, television viewing does lead to higher levels of negativistic interpersonal interaction. The findings from all of the field experiments are discussed with regard to their clinical relevance for mental health professionals.

First episode schizophrenia: Effect on the family

Dr M. G. Livingstone, University of Glasgow

A sample of 49 schizophrenics in their first episode of the illness was recruited. Data were collected on psychopathology, cognitive functioning and CT scans, together with an assessment of the relatives' psychiatric and social functioning. This paper reports on the relative' psychosocial status throughout the year following initial episode of schizophrenia. An association between the relatives' adjustment and patient's symptoms is described.

Auditory hallucinations and subvocal speech in schizophrenia

Drs P. A. Bick and M. Kinsbourne, University of Dundee

Hallucinations have variously been regarded as an expression of excess (disinhibited) brain activity or products of adaptive behaviour, either searching for organisation in a chaotic array or motivated by dynamic imperatives. We have examined whether auditory hallucinations arise from brain dysfunction, or compensate for it, with respect to the recurrent claim that these are accompanied by subvocalisation.

We carried out a study in 18 schizophrenic patients who complained of voices. Each patient was asked to perform three tasks, one of which (holding the mouth wide open), has been shown to prevent subvocalisations. The control tasks were to make a fist with both hands and squeeze tightly and a facial control manoeuvre, screwing the eyes tightly. The interviewer was unaware of the experimental hypothesis. Fourteen of the patients reported that their voices went away when they undertook the manoeuvre that precluded subvocalisation.

To investigate the generality of this phenomenon, 35 normal subjects were hypnotised and given the suggestion to hear voices. Twenty-one accepted this suggestion. Subjects were instructed to perform the same manoeuvres as the schizophrenic group. The mouth opening manoeuvre abolished hallucinations in 18 of the subjects. This finding aligns the schizophrenic's experience with behaviour to which normal subjects may 'unconsciously' resort.

These results confirm that subvocalisation accompanies

auditory hallucinations in schizophrenics. Previous studies have included no specific or controlled manipulation of this phenomenon, and it could not, until now, be excluded that schizophrenics shadow in whispers, voices that they hear. Our data demonstrate that schizophrenics actually generate voices, they do not merely shadow them. A theory can be propounded that hallucinations represent verbal thoughts, disinhibited into vocal activity. This might explain why neuroleptics are often ineffective in counter-acting voices. This might also explain why the patients in this study were profoundly unimpressed by the revelation that they could easily abate their troublesome voices. Treatment strategies for troublesome hallucinations need to be reassessed in the light of this finding.

Cerebral perfusion in schizophrenia

Drs R. J. Mathew and W. H. Wilson, Duke University Medical Centre, USA

Regional cerebral blood flow (rCBF) measurements were obtained with the ^{133}Xe inhalation technique in 100 patients with a diagnosis of schizophrenia and an equal number of normal controls matched on age, sex and cerebral dominance. The patients were screened with Schedule for Affective Disorders and Schizophrenia and the diagnosis was based on DSM-III criteria. Psychopathology was quantified with Brief Psychiatric Rating Scale (BPRS) and a standardised scale for positive and negative symptoms of schizophrenia. All cerebral blood flow measurements were conducted in a semi-dark, quiet room under identical conditions. Thirty patients were kept drug-free for a minimum of two weeks before the rCBF measurements. All subjects were required to abstain from caffeine and tobacco for at least three hours before measurements. Normals showed increased frontal perfusion in comparison to the rest of the brain. The patients, however, showed reduced frontal-posterior gradient in cerebral perfusion in comparison to the controls. The relationships between rCBF and such clinical variables as duration of the illness, family history of schizophrenia, number of previous hospitalisations, symptoms of schizophrenia and treatment with neuroleptics and relevant physiologic variables (CO_2 , hematocrit) were examined.

Brain changes during ECT using magnetic resonance imaging

Drs A. J. Mander, A. Whitfield, D. M. Kean, M. A. Smith, Miss R. H. B. Douglas and Professor R. E. Kendell, University of Edinburgh

Fourteen patients satisfying RDC criteria for a major depressive episode had an NMR scan before and immediately after the first and approximately the last treatment of a course of ECT. Subsequently three of the patients were scanned at intervals over the following 24 hours. No progressive changes in the T1 relaxation time were noted over the course of ECT, but acute changes did occur after each individual treatment, reaching a maximum 4–6 hours following the fit. The changes appeared to be generalised in nature and there was no evidence of lateralisation in those patients given unilateral ECT.

The data are consistent with the observation that the blood brain barrier breaks down during a fit and it is of particular interest that the maximum change occurs some hours later. The results must be viewed as encouraging, since there was no evidence of permanent or progressive structural change as a result of treatment. More work is

now needed on the temporal changes of T1 with a larger patient sample and whether these changes are related to improvement or side effects. The underlying physiological basis of the change in T1 is still to be elucidated.

Minor psychiatric morbidity in people with epilepsy: Evidence for a gender difference

Professor G. W. Fenton, University of Dundee

All the patients with epilepsy in a total practice population of 75,200 were identified. Those agreeing to participate in the study were reviewed by their GP and visited at home by a research health visitor. Those aged 16 years or over completed the Crown Crisp Experimental Index (CCEI). A control sample of non-epileptic patients from the same practices, matched for age, sex and social class was also examined. The male epileptic patients had a higher prevalence of certain neurotic symptoms and traits. This gender difference related to seizure frequency and employment status, but not to polytherapy, serum anticonvulsant levels nor class of epilepsy.

Mood disorders in epilepsy: A survey of psychiatric patients

Drs S. S. Palia and M. A. Harper, Glan Rhyd Hospital, Wales

In-patients and day-patients with epilepsy in a general psychiatric service were surveyed. Fifty-three patients able to co-operate in a detailed assessment were studied using the Hamilton Rating Scale and the Beck Depression Inventory. About one-third (32%) of the patients had serious depressive illness mostly classified as non-endogenous on the Newcastle Index.

Neurophysiological factors were overshadowed by the psychological and social problems generally found in depressed patients. Almost all of the depressed epileptics gave histories of repeated previous deliberate drug overdose and a past history of depression. The multifactorial nature of depressive states in epilepsy is emphasised.

It is suggested that the occurrence of intense short-lived depressive moods associated with suicidal behaviour in epileptics may be due to the release of affect secondary to fluctuations in consciousness in vulnerable individuals rather than to specific neuro-physiological or pharmacological factors.

Psychopathology of the Gilles de la Tourette syndrome

Drs M. Robertson, M. Trimble and A. Lees, The National Hospital, London

The history of an association between psychopathology and the Gilles de la Tourette Syndrome (TS) is long, particular reference being made to obsessive compulsive behaviour, aggression, dysphoria and changes in neuro-psychological function.¹ However, most studies are anecdotal and clinical, often relying on a small number of cases. One group attempted a systematic evaluation of psychopathology among TS subjects and not only failed to find an increased amount when compared to a general psychiatric outpatient population, but reported nothing specific.² We have carried out a study of 90 patients with TS, using standardised psychiatric rating scales and specialised tests including neuropsychological testing, EEGs and CAT scans. Psychopathology was prominent. In particular, patients exhibited depression, hostility and obsessiveness. Depression was not related to the taking of medication, while aggression, hostility and obsessiveness

were significantly associated with some core features of the syndrome, namely copro- and echophenomena. Links between neurological and EEG abnormalities were minimal.

Organic pathology and psychiatric morbidity in neurological referrals to a consultation/liaison service

Drs A. Schofield and A. Duane, Cork Regional Hospital, Ireland

This study analyses the patterns of referral of neurological in-patients to find out in what way they differ from referrals from the whole general hospital. The symptomatology of those patients with functional neurological illness is explored and the psychiatric morbidity of those patients with organic illness is evaluated. Neurology referrals differ from general hospital referrals in reasons for referral and in patterns of diagnosis. The commonest neurological illnesses referred are epilepsy, Parkinsonism and cervical spondylosis. The commonest conversion symptoms seen are pain and secondarily pseudoseizures. The psychiatric diagnosis made in those patients with functional pain varies with the site of the pain. These two conversion symptoms, pain and pseudoseizures have differing ages of onset and prognoses. A number of patients were given no psychiatric diagnosis and the reasons for this are discussed.

It is concluded that for the psychiatric treatment and management of neurological referrals to a psychiatric consultation/liaison service, a detailed knowledge of the patterns of symptomatology and psychiatric morbidity found in these patients is of benefit.

An electrophysiological study of senile dementia of the Alzheimer type

Drs P. A. Williams and G. H. Jones, University of Wales College of Medicine, Cardiff

Event-related potentials were studied in senile dementia in 20 subjects and compared with normal controls. The auditory evoked potential to a target stimulus consists of the N100, P200 and P300 components. The N100, N200 and P300 are all delayed in latency in this group of subjects. During the procedure the subject is required to press a button to detect the target stimulus and reaction time data are collected also, the latter is also delayed in dementia. A number of authors have also recently published data indicating delays in the P300 components in presenile dementia and there has been work on reaction time experiments in the literature. The authors describe their results and attempt to discuss them in terms of a perspective of information processing theory as a means of understanding cognitive processes in dementia.

The effect on the hypothalamus of an oestrogen provocation test in pre-operative transsexuals

Dr M. T. Haslam, Clifton Hospital, York

Donner working in Berlin noted that the differentiation into male and female hypothalamic types can be distinguished with reasonable reliability using an oestrogen provocation test and monitoring FSH and LH output for four days

thereafter. He noted an increased number of female type responses in male homosexuals whom he described as of effeminate type. It was hypothesised that in transsexuals and possibly some transvestites this phenomenon might also occur, thus confirming the transsexual's belief that he has a female brain functioning in a male body.

To test this hypothesis transvestites and transsexuals living in the York/Leeds area who were not on hormones and were prepared to take the test were screened with an oestrogen provocation test. A small control group was also utilised to form a comparison. The results of this trial are presented. It is noted that the incidence of female-type responses, while not reaching statistical significance in view of the smallness of the group, nevertheless show a considerably greater number than would be expected by chance. The significance of this result is discussed.

Increased bromide levels in serum and hair during lithium treatment

Drs C. A. Campbell, Hellesdon Hospital, Norwich; M. Peet, Northern General Hospital, Sheffield and N. Ward, University of Surrey, Guildford

Lithium has been shown to affect serum levels of a number of elements, such as calcium and magnesium.¹ A recent report has suggested an elevation in serum bromide levels in patients on long-term lithium carbonate treatment.²

In the study to be presented, the concentration of bromide was measured by neutron activation analysis in samples of serum from 32 patients on maintenance lithium carbonate and from 32 age and sex matched healthy controls. Whole blood and hair samples were also taken from a number of patients and controls. Bromide levels were found to be significantly higher in the serum and hair of patients in the lithium group compared to the control group (serum bromide $P0.05$; hair bromide $P0.0001$ two-tailed t test). The possible effect of this increase and the mechanism causing it is discussed.

Alcohol and drug problems in the elderly

Alcohol and Old People

Dr John P. Wattis, St. James's University Hospital, Leeds

Despite the increased proportion of old people in Western societies since the last World War and despite upward trends in alcohol consumption associated in part with industrialised production and marketing methods, doctors still do not expect to see elderly alcoholics or drug abusers. Following a recent upsurge of interest in this area it is becoming evident that alcohol abuse in old people is more common than was previously apparent. Evidence is also accumulating that the clinical presentation of alcohol abuse in old people is often different from the presentation in younger people and that alcohol abuse in old people far from being a harmless consolation leads to serious physical and psychological harm. With the information available it is now becoming possible to look at possible strategies for the prevention, early detection and treatment of alcohol abuse in old people.

Surveys have repeatedly shown that in different societies

old people consistently drink less alcohol than their younger counterparts. One study in Scotland showed, for example, that only 43% of elderly men and 22% of elderly women were 'regular drinkers' compared with 74% and 46% of the total male and female populations. This and similar studies in other countries can be criticised on two main counts: (a) the definitions of 'regular' or 'heavy' drinking are the same for young and old, male and female, despite evidence that women and old people tolerate alcohol less well than young men; (b) it is quite possible that old people under-report alcohol consumption for a variety of reasons. Epidemiological studies of the prevalence of alcohol abuse as opposed to heavy drinking suggest that in some cultures at least, female prevalence for alcohol abuse peaks in the over-70 year-old age group. This finding concurs with clinical studies which have suggested that there is a late-onset group of female alcoholics who presumably take to excessive drinking for the first time in response to the stresses of ageing including bereavement and loneliness.

The clinical presentation of alcohol abuse in old age is also distinctive. Although some elderly alcoholics are longstanding survivors of chronic excessive drinking, others present with problems such as repeated falls, self-neglect and confusion, typical 'non-specific presentations' of disease in old people. In these people in particular the true diagnosis is easily missed.

The harm that results to old people who drink excessively is similar to the harm that occurs to younger drinkers. Old people may be more at risk for alcoholic dementia and for problems associated with poor nutrition. In addition they may have different patterns of drinking and supply than younger people. They may be dependent on others to supply alcohol within the home or may even be encouraged to drink by other younger alcoholics who regard the old person's pension as a useful source of alcohol for their own consumption.

The detection of alcohol abuse in old people thus demands a high level of awareness on the part of medical and social services staff and on public awareness that heavy drinking in old people is harmful and should not be dismissed with such phrases as 'it's all she's got left'. Treatment is in two phases. The acute phase involves alcohol withdrawal with sedative cover usually as an inpatient where associated vitamin deficiencies and other medical problems can be dealt with. Following this it is essential whenever possible to alter the patient's social support network so that excessive drinking is no longer encouraged. Prevention of alcohol abuse in old people raises similar issues to prevention in younger people though it may be that additional social measures such as more constructive opportunities in life for recently bereaved old people could have a part to play in the prevention of the late onset type of alcoholism.

The little explored area of drug abuse in old people is briefly discussed. The problems of active and passive abuse of prescribed drugs is considered and the positive role of the medical profession in reducing this problem is stressed.

A case register study of elderly alcoholics in Edinburgh

Dr K. J. B. Rix, University of Leeds

The Edinburgh Psychiatric Case Register was used to identify all alcoholics aged 60 years or more who made a new contact with the Edinburgh psychiatric services over a

six month period. A sex-matched comparison series of non-elderly alcoholics was obtained in the same way. Subjects were interviewed and questioned concerning demographic information, alcohol consumption, possible alcohol-related disabilities, symptoms of alcohol dependence and social functioning. Assessments were made of cognitive functioning. Thirty-four elderly and 32 non-elderly alcoholics were notified. At least 90% in both groups were traced and interviewed. The elderly alcoholics differed from the young alcoholics in the following respects: diagnosis of chronic brain disease, source of referral, service in which treated, outcome of marriage, type of accommodation, occupational status, alcohol consumption, history of parasuicide, alcohol-related crime, age of onset of alcoholism, social range, number and range of current long-term difficulties and experience of difficulties with work, police and finances. The differences in performance on cognitive tests disappeared when elderly alcoholics with a diagnosis of chronic organic brain disease (i.e. dementia or Korsakoff's psychosis) were excluded.

Understanding alcohol abuse in the older person

Mr C. J. Goodman, Social Services Department, London Borough of Richmond-upon-Thames

The elderly population is increasing and those responsible for the resources available will need to be more aware of the particular problems surrounding the process of growing old. One of the consequences of growing old is the increasing likelihood of loss. Losses can include the loss of home, status, children, job, independence, spouse, etc. Due to the paucity of services and time available, the counselling and understanding of the processes of loss are often insufficient to allow the old person to cope adequately. As a result alcohol is being used by the old person to cope with the stress caused by the loss.

There are, however, two types of elderly drinker, defined as the long-term user and the 'solution' drinker. The long-term drinker is far more difficult to help and is more likely to be labelled as 'hopeless alcoholic', due largely to the carer's inability to effect any change. The 'solution drinker', however, can be helped by the appropriate use of counselling and support and therefore provides us all with a chance to effect change in lifestyle. Although these two categories of drinker are different and their response is different, the use of the term 'alcoholic' does not help either the old person or the carer to understand the cause of the drinking or to help in the process of change. Indeed one function of the labelling process is to provide a comfortable definable status or sub-group in which the bearer can receive the comfort and support of a similar group of people. The effect of the label 'alcoholic' is to ensure that the person so described will behave in a way which will justify his inclusion into such a group. As professional carers we must be careful that the language we use to our clients does not exacerbate the 'condition' with which we have been asked to help.

Group therapy with elderly female alcoholics

Dr E. Guthrie, Manchester Royal Infirmary

Approximately 1 in 15 patients referred to alcohol treatment units are over 65. There is conflicting evidence as to whether these patients' pattern of drinking and treatment needs are different to those of younger patients with alcohol problems. A group for elderly female alcoholics was set up

on the ATU at Withington Hospital in 1983. The setting up of this group, its course over two years and the practical problems that were encountered are described. The main themes of the group are outlined and suggestions for future management of such patients are made

Suicide

Some observations on the epidemiology of suicide

Dr P. Sainsbury, Emeritus Consultant Psychiatrist, Graylingwell Hospital, Chichester

The singular value of suicide statistics to psychiatric epidemiology is illustrated by: (a) recent trends in England and Europe, (b) the relations between these trends and changes in socio-economic conditions in Europe, (c) some differences between social and other characteristics of cases of suicide and a sample from the general population which indicates who is at risk, and the (d) extent to which suicides have a recognisable and treatable psychiatric illness and the preventive implication of this.

The recent epidemiology of suicide in England and Wales

Dr G. M. G. McClure, Westminster Children's Hospital, London

The suicide rate for both sexes in England and Wales reached a post-war peak in the early 1960s and then declined until 1975. This decrease was associated with a fall in the number of suicides by poisoning with domestic gas, which was being detoxified during this period. The greatest decrease in suicide rate was for people over 45 years. Between 1975-1985 the suicide rate for females levelled off, but there has been a steady rise in suicide rate for males during this period. The greatest increases occurred for poisoning with vehicle exhaust gas and by hanging, strangulation and suffocation, while there was a decrease in poisoning with solids and liquids. There has been a substantial increase in suicide rate between 1975-1985 for males aged 25-44 years.

Prison suicides

Dr S. Beckett, Royal Edinburgh Hospital

A recent study has shown that suicide is the largest single cause of death in prison and accounts for approximately a third of the total number in this setting. Concern has been expressed about these deaths and the question most frequently asked is whether they could have been prevented. When considering possible preventive strategies, one has to ask if the characteristics of those who commit suicide in prison are similar to those in general population and whether any groups or sections of the prison population appear to be particularly vulnerable.

This paper addresses these questions using data from studies carried out both here in the UK and the United States. It also includes results from a study which examined the previous psychiatric contact of a group of prisoners who subsequently committed suicide.

The epidemiology of violent and unnatural death in one catchment area

Mrs E. King and Dr B. M. Barraclough, University of Southampton

Victims of violent death were identified from death registration information sources. Demographic, social, circum-

stantial and medical data were extracted from inquest files and hospital case notes. Patient status at the time of the event leading to death was ascertained for each referred psychiatric patient. In the eight years up to the end of 1981 there were 412 potentially self-inflicted deaths among catchment area residents which were subject to inquest by one of 22 coroners in England and Wales. 245 suicide (S), 126 accidental death (A) and 41 undetermined death (OV) verdicts were returned. The 1981 Census population of the Southampton Department of Psychiatry Catchment area was 297,000 (237,000 aged 15+). Between 1974 and 1982 the average annual catchment area female violent death rate (S+A+OV) of 15.3/100,000 population aged 15+ was identical with the corresponding England and Wales rate; the catchment area male violent death rate of 28.5% was 19% higher than the England and Wales rate with the increase entirely in the suicide rate.

Of the whole group of 412 violent death victims. (a) 56% (60% S; 50% A; 54% OV) were known from records to have been referred to a psychiatrist at some time; (b) 20% (21% S; 18% A; 27% OV) were actually receiving psychiatric care when they died; (c) 4% (6% S; 1% A; 2% OV) were psychiatric in-patients; (d) 16% (15% S, 16% A; 24% OV) were current psychiatric out-patients. During any year less than 2% of the catchment area population was recorded by the Southampton Psychiatric Case Register as being in contact with its psychiatric services.

Brief psychotherapy

Assessing and treating families of in-patients

Drs B. K. Rosen and P. Jarrett, Guy's Hospital, London

Work with families of in-patients requires adaptation of family therapy practice which has largely concentrated on intact families. The obvious difference is that one member of the family has been identified as ill by both the family and the helping organisation. The hospital has a special relationship with the sick member which must be addressed in work with the family. Perceptions of family relationships are likely to be distorted by the admission and an initial task for the unit is to develop an assessment which takes this into account. We have found a useful tool in the McMaster Model of Family Function which provides a systematic and structured assessment procedure. The McMaster model leads to the construction of a problem list which can also be incorporated into ward management and treatment procedures. Interviewing families in this way allows joint planning of treatment goals including task setting for weekend leave and discharge. Particular aims of family therapy include the following: (a) registration of the status of the patient and his illness within the family; (b) countering the family's sense of failure, guilt and suspicion of the treatment setting; (c) effecting change within the family system and sub system which can be maintained after discharge; (d) organising ward treatment programmes which are specifically targeted at the patient's problems within the family.

Assessing the individual

Dr A. Ryle, St Thomas's Hospital, London

It is proposed that a suitable first intervention for most neurotic and personality disordered patients is a focused time-limited (12 to 16 sessions) individual therapy. If adequately focused this will be sufficient treatment for most

patients and a suitable assessment procedure for those with more severe disturbances. Patients with severe drug or alcohol abuse or psychotic illness will be excluded and some patients may be better treated in family or marital therapy. The aim of the psychotherapy is to alter those patterns of relationships and self-attitudes underlying the patient's distress. Some patients, for example those with severe eating disorders or marked obsessive-compulsive disorders and some phobias, may need prior or concomitant behavioural treatment. Patients with major depressive symptomatology may need prior antidepressant medication.

For those taken on for the brief therapy the central task of the assessment phase, which usually lasts for four sessions, is to derive clear descriptions of the patient's repeatedly used maladaptive procedures. These descriptions may include hypothesising some mental processes of which the patient is unaware. By 'procedures' is meant the sequence of belief, anticipation, choice, action and evaluation used by the patient to organise purposive action; shorthand descriptions of neurotic procedures have been described as traps, dilemmas and snags. Explanations and descriptions of these are listed in the 'psychotherapy file' which patients are given to read after the first session. In reformulating patients' problems, therapists will draw upon clinical data, both historical and observational and on psychological test procedures and on the work which patients themselves will do. This will include self-monitoring of symptoms, other forms of writing and paper and pencil tests as well as the patients' reading of the psychotherapy file. By the fourth session it is usually possible for the patient and therapist to agree to a written list of target problems (TPs) representing usually the presenting complaint and of target problem procedures (TPPs). These lists identify what it is that therapy aims to change. Subsequent therapeutic work, whether behavioural, cognitive or interpretive or some combination of these, will always be related to these descriptions. Patients are given the task of focused diary keeping in relation to these descriptions to enable them to recognise and hence change their recurrent use of these ineffective procedures. Change in respect of the defined problems and procedures will be rated by patients regularly through the rest of therapy.

Target problem procedures define for the patient his appropriate responsibility for his difficulties while diminishing his sense of powerlessness, confusion and irrational guilt and they serve to emphasise that both conceptual and behavioural change are called for. For the therapist, the list provides a clear guide to his interventions and a basis for choosing methods and for assessing progress. In more disturbed patients, only selected identified problems may be tackled in the course of the brief therapy but the patient's ability to work and the effects of such work, will provide a basis for deciding whether further treatment is necessary or helpful. This approach minimises the risk of regressive dependency on the part of the patient and guards against a premature or unnecessary commitment to longterm therapy.

Brief psychotherapy in crisis intervention

Dr Shakir Ansari, St Thomas' Hospital, London

The work of a 'crisis intervention team' involving domiciliary assessment and management is described, as part of a comprehensive district-based service. A wide spectrum of psychiatric disorders are seen and treated, ranging from

psychotic illness, to major depression, neuroses and adjustment reactions. Treatment is broad-based, including medication and psychological methods.

It has been noted that the use of psychotherapeutic techniques are of value, being commonly employed. Using the crisis team at the mental health advice centre as a model, it can be seen that psychotherapy, especially brief or time-limited, fits in well with the idea of a comprehensive district-based psychiatric service.

A trainee's experience and opinion

Dr B. J. Brockman, Guy's Hospital, London

The paper addresses the historical setting of a 7 year training period in South East Thames as preparation for work as a general adult psychiatrist. The difficulties arising in training will be discussed, paying particular attention to personal and temporal issues. The format of therapy training will be discussed with reference to different therapeutic techniques, supervision, formal theoretical teaching and a research project. The application of the therapeutic techniques will be discussed in relation to work as a general psychiatrist. In conclusion, the relationship of therapy training and work in the NHS setting is discussed.

Poster presentations

Psychological sequelae of kidney donation: A 5-10 year follow-up study

Drs Vimal Kumar Sharma, Fazakerley Hospital, Liverpool and M. David Enoch, Royal Liverpool Hospital, Liverpool

Twenty-three out of 30 potential kidney donors were followed up after a period of 5-10 years. Fourteen were donors and the other nine subjects who were not allowed to donate kidneys on medical grounds constituted the control group (non-donors). Psychiatric morbidity was assessed by using the Present State Examination (PSE) Interview Schedule. CATEGO-ID Programme identified one case in the donor group and one case in the non-donor group. The psychiatric problems of both the cases were unlikely to be related to the kidney transplantation. The majority of the donors, irrespective of the outcome of the transplant procedure, expressed positive feelings towards kidney donation. This study suggests that the kidney donation does not cause adverse long-term psychological sequelae.

The use of electroconvulsive therapy in the elderly

Drs S. M. Benbow and D. J. Jolley, Central Manchester Health Authority

A retrospective study was carried out of 122 patients who received 193 courses of ECT under the care of the psychogeriatric service at the University Hospital of South Manchester between 1976 and 1982. The characteristics of the patients, their treatment details, response and outcome are described. In most cases (96%) the major diagnosis was a depressive illness. Bilateral ECT was administered throughout 95% of courses with a mean of 8.3 treatments per course. Although many patients had a physical problem (51%), serious complications of treatment were rare and 80% of patients were discharged well or substantially improved. About one-third of patients had another one or more courses of ECT during the follow-up period. Subsequent courses of ECT were not likely to be longer than the initial course nor was ECT less likely to be effective. It is

concluded that ECT is an effective and safe treatment in depressed elderly people.

Brain perfusion during epinephrine induced anxiety

Drs R. J. Mathew and W. H. Wilson, Duke University Medical Center, USA

Regional cerebral blood flow (rCBF) was measured with the ^{133}Xe inhalation technique twice at an interval of 30 minutes in 30 drug-free patients with a diagnosis of generalised anxiety disorder (based on DSM-III and SADS) and an equal number of normal volunteers. One-half of the patients and controls received intravenous infusion of 0.2 mcg/kg per minute of epinephrine in saline for five minutes immediately before the second measurement. The remaining subjects received saline infusion between the two measurements. The subjects were assigned to epinephrine and saline groups on a random basis and infusions were given under double-blind conditions. All measurements were carried out in a semi-dark, quiet room under identical laboratory conditions. During each rCBF measurement blood pressure, pulse rate, end-tidal levels of carbon dioxide, state anxiety (State Trait Anxiety Inventory), somatic symptoms of anxiety (with a standardized rating scale) and hematocrit were measured. The two groups of subjects were compared on these indices and their inter-relationships were examined. The anxiety patients who received epinephrine showed a significant increase in state anxiety and decrease in both right and left hemispheric flows during the second run. This finding persisted even after the effects of carbon dioxide changes were partialled out. The rCBF decrease was most pronounced in the left hemisphere. Correlations between anxiety related clinical and physiological indices and rCBF (resting and after epinephrine) were computed in both groups of subjects.

A double-blind trial of carbamazepine and haloperidol in mania

Dr D. Brown, Professor T. Silverstone and Dr J. Cookson, St Bartholomew's and the London Hospitals

Is carbamazepine (CBZ) as effective as haloperidol (HP) in the treatment of acute mania and is it as well tolerated? To answer these questions 17 hospitalised manic patients fulfilling DSM III criteria for mania were included in a double-blind trial of CBZ (starting dose 400 mg/day max. 1600 mg/day) and HP (starting dose 20 mg/day max. 80 mg/day). Procyclidine (PCD) up to 30 mg/day was allowed for extra-pyramidal symptoms. If required, chlorpromazine (CPZ) could be used as a 'rescue' drug. Clinical ratings using the Young and the Petterson mania scales were made on days, 0, 1, 3, 7, 14, 21, 28 and 42.

Seven of the nine patients on HP compared to two of the eight on CBZ failed to complete the four week trial. Failure to complete occurred either because of side effects (3HP) lack of efficacy (2 CBZ, 3 HP) or a switch to depression (2 HP). HP appeared to act more quickly; the mean Young score fell from 29 to 20 in three days compared to no change in the CBZ group. Thereafter the CBZ group improved steadily with the Young score falling from 31 to four in four weeks. Extra-pyramidal side effects were common on the HP group (accounting for three dropouts); gastrointestinal symptoms were more prominent in the CBZ group, but did not lead to any drop outs.

While the two drugs were broadly similar in terms of efficacy, tolerability was noticeably greater with CBZ. CBZ

is thus likely to prove a useful drug in the management of mild to moderate mania

Anticonvulsant medication in a mental handicap hospital: 1972-1982

Dr L. C. Sheppard, University of Dundee

The prescription sheets for all patients in a mental handicap hospital on one day in 1972 and on the same date in 1982 were examined to identify trends in anticonvulsant medication over a 10 year period. There was a reduction in size of the hospital population associated with fewer very young and mildly handicapped persons. The prevalence of anticonvulsant prescribing fell slightly over the decade under study with a dramatic fall in the use of phenobarbitone. This decline is paralleled with an increase in carbamazepine prescribing. Other changes include the use of sodium valproate in a significant minority of patients and the occasional use of clonazepam in 1982, while phenytoin remains a first rank anticonvulsant throughout the period under review. The proportions of patients on polytherapy have not changed over the 10 year period, though the contribution of phenobarbitone to the combined drug regimes has reduced significantly.

Practice in a provincial drug dependency clinic

Dr J. Marks, Halton General Hospital, Runcorn, Cheshire

Widnes and Runcorn (pop. 150,000) have had a drug dependency clinic offering a maintenance opiate management for several years. Bootle had no such clinic until 1985, but counselling, withdrawal and detoxification had been available. It was hypothesised that illicit drug use would have spread wider in Bootle and Widnes because of this difference in service provision and that referrals would reflect this. This was found to be the case. Follow-up of chronic drug addicts in Widnes is reported. This study confirms Vaillant's view of drug dependency as a chronic relapsing condition with a remission rate of roughly 10% per annum. If the patient can be sustained at a drug clinic, the prognosis reaches a 50% likelihood of recovery after 10 years.

Treatment of alcoholism in Kuwait: A prospective follow-up study

Drs A. M. Bilal, J. Kristof, A. Shaltout and M. F. El-Islam, Kuwait University

The outcome of routine drug supportive psychotherapy treatment of 100 patients with alcohol-related problems in Kuwait's only psychiatric hospital was evaluated on four six-month intervals. Patients were assessed on nine post-treatment questions which reflect patient's improvement or deterioration. Correlation of follow-up changes to pre-treatment patient data shows that non-Kuwaitis do better than Kuwaitis in resuming employment and social re-integration. Patients on chronic benzodiazepine prescription were less likely to become abstinent, had poor social re-integration and more re-admissions. Good relationships with the family of origin were clearly associated with a better treatment outcome.

Scores of weighted follow-up findings were calculated to assess the patient's status at each follow-up. The patient's progress during the whole follow-up period was measured by the direction of slope calculated from linear regression model for individual scores. The relationship between pre-treatment conditions and patterns of follow-up was

POSTER PRESENTATIONS

evaluated cross-sectionally (mean scores) and longitudinally (direction of slope). A pattern of shift emerged where different patients' groups crossed over to the opposite end of score scale. Kuwait society's indulgent attitudes towards Kuwaiti patients with alcohol related problems in employment have to be changed and utilisation of the role of the Arab extended family in therapy is stressed.

Psychiatric emergencies at King Khalid University Hospital *Dr A A El-Gaaly, Faculty of Medicine, Riyadh, Saudi Arabia*

In this study, 100 consecutive emergency psychiatric cases are studied. These were all new referrals from the accident and emergency department to the psychiatric team. Demographical, clinical data, as well as management offered are compared for males and females. The total group are compared with the results of a British study. Differences are discussed. The findings suggest that a psychiatric emergency service should be available to all referrals 24 hours a day. It is not only a needed service, but it also offers important learning opportunities to residents and staff.

Minor physical anomalies as a biologic marker for behavioural disorder

Dr J C Pomeroy, SUNY, New York, USA

The importance of subtle neurologic or neurophysiologic abnormalities as predictors of childhood and adult psychiatric disorders or indicators of underlying organic brain disorder in behaviourally disturbed children is of con-

siderable dispute. Minor congenital deviation in physical characteristics, believed to represent first trimester insults to the foetus, have shown a relationship with childhood behavioural and educational problems as well as psychosis in all ages. Early enthusiasm for the measurement of minor physical anomalies to indicate future disturbance and need for intervention has been somewhat tempered by more recent studies.

In the course of a comparison study between children designated emotionally disturbed or learning disabled by the educational system, an opportunity arose to measure physical anomalies in this population. The school nurse rated 93% of the 139 pupils for physical anomalies in the centre for emotionally disturbed grade schoolers. Sixty-eight per cent of this population were also rated by a second examiner. Scales assessing behaviour, medical history and social characteristics were completed by the teachers, social workers and school nurse. Demographic information as well as intellectual and educational evaluations were available from school records.

Nineteen girls and 111 boys aged 5-12 years (mean 9.4 years) with a mean IQ of 88 (ranged 42-126) were examined. All were designated emotionally disturbed. Inter-rater agreement for the presence of anomalies was comparable to other studies but exposed the subjectivity of a number of the measures. The level of anomalies was not as high as had been found in clinically diagnosed groups, but using the data available from this study, and from a review of the literature, an assessment of the relevance of physical anomalies for specific behavioural syndromes will be addressed.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).
